

Joint Estimation and Localization in Sensor Networks

Nikolay Atanasov, Roberto Tron, Victor M. Preciado, and George J. Pappas

Abstract—This paper addresses the problem of collaborative estimation and tracking of dynamic phenomena via a wireless sensor network. A distributed linear estimator (i.e., a type of a *distributed Kalman filter*) is derived. We prove that the filter is mean square consistent when estimating static phenomena. In large sensor networks, it is common that the sensors do not have good knowledge of their locations, which affects the estimation procedure. Unlike existing approaches for target tracking, we investigate the performance of our filter when the sensor poses need to be estimated by an auxiliary localization procedure. A distributed Jacobi algorithm is used to localize the sensors from noisy relative measurements. We prove strong convergence guarantees for the localization method and in turn for the joint localization and target estimation approach. The performance of our algorithms is demonstrated in simulation on environmental monitoring and vehicle tracking tasks.

I. INTRODUCTION

A central problem in networked sensing systems is the estimation and tracking of evolving physical phenomena. Examples include environmental monitoring [1], [2], surveillance and reconnaissance [3], [4], and social networks [5]. Individual sensors typically receive partially informative measurements which are insufficient to estimate the target state in isolation. To address this challenge, the sensors need to engage in information exchange with one another and solve a distributed estimation problem. To complicate matters, it is often the case that the sensors need to know their own locations with respect to a common reference in order to utilize the target measurements meaningfully. Hence, they face a joint *localization* and *estimation* problem. Existing work in distributed target estimation assumes implicitly that the localization problem is solved, while all the literature on localization does not consider the effect of the residual errors on a common estimation task. The goal of this paper is to show that the two problems can be solved jointly, and that, with simple measurement models, the resulting estimators have strong convergence guarantees.

Assumptions and contributions. We assume that the sensors obtain linear Gaussian measurements of the target state and repeated sequential measurements of their relative positions along the edges of a graph with known covariances. Our contributions are as follows:

- We derive a distributed linear estimator for tracking dynamic targets. We prove that the filter is mean square consistent in the case of a static target.
- We provide a distributed algorithm for sensor localization from sequential relative measurements and prove mean

square and strong consistency.

- We prove that the joint localization and estimation procedure has arbitrarily small asymptotic mean square error

Related work. Our target tracking algorithm was inspired by Rahnama Rad and Tahbaz-Salehi [6], who propose an approach for distributed *static* parameter estimation using nonlinear sensing models. We specialize their model to heterogeneous sensors with linear Gaussian observations, derive the update step of the resulting linear estimator, and show stronger convergence results (mean-square consistency instead of weak consistency). Finally, we add a prediction step to the filter in order to handle *dynamic* targets. Our filter is similar to the Kalman-Consensus [7], [8] and the filter proposed by Khan et al. [9], [10] but uses different gains in the update step and the performance guarantees (for static targets) we obtain are stronger. Khan et al. [9] show that their filter can track a dynamic target with bounded error if the norm of the target system matrix is less than the network tracking capacity. Shahrapour et al. [10] quantify the filter's estimation performance using a global loss function and show that the asymptotic error depends on the loss function decomposition. Kar et al. [11] study distributed static parameter estimation with nonlinear observation models and noisy inter-sensor communication. Related work also includes [12], which combines the Jacobi over-relaxation method with dynamic consensus to compute distributed weighted least squares.

Our localization algorithm follows the lines of the Jacobi algorithm, first proposed for localization in sensor networks by Barooah and Hespanha [13], [14]. In contrast to their approach, we consider repeated relative measurements and show strong convergence guarantees for the resulting sequential algorithm. Other work in sensor network localization typically considers nonlinear and less informative measurement models. For instance [15], [16], [17], [18] address range-only localization, which is challenging because a graph with specified edge lengths can have several embeddings in the plane. Khan et al. [19] introduce a distributed localization algorithm, which uses the barycentric coordinates of a node with respect to its neighbors and show convergence via a Markov chain. Diao et al. [20] relax the assumption that all nodes must be inside the convex hull of the anchors. Localization has also been considered in the context of camera networks [21].

None of the papers mentioned above, however, consider state estimation and localization jointly. While the joint problem can be cast as a large distributed estimation task and addressed with existing methods (e.g. the Kalman-Consensus filter [7], [8]), the resulting solution will have each sensor estimate the locations of *all* other sensors in the network. This has slow convergence and is infeasible for large networks as it requires repeated exchange of information that scales with

the size of the network. The proposed joint algorithm resolves this challenge and in addition keeps the update rules linear.

Paper organization. The joint localization and estimation problem is formulated precisely in Sec. II. The distributed linear estimator for target tracking is derived in Sec. III assuming known sensor locations. A distributed Jacobi algorithm is introduced in Sec. IV to localize the sensors using relative measurements when the true locations are unknown. Mean-square and strong consistency are proven. In Sec. V, we show that the error of the target estimator, when combined with the localization procedure, remains arbitrarily small. All proofs are provided in the Appendix.

II. PROBLEM FORMULATION

Consider a sensor network composed of n sensors with states $\{x_1, \dots, x_n\} \subset \mathcal{X} \cong \mathbb{R}^d$. The state of a sensor may include its position, orientation, and other operational parameters but we will refer to it, informally, as the sensor's location. The communication network interconnecting the sensors is represented by an undirected graph $G = (V, E)$ with vertices $V := \{1, \dots, n\}$ corresponding to the sensors and $|E| = m$ edges. An edge $(j, i) \in E$ from sensor j to sensor i exists if they can communicate. The set of nodes (neighbors) connected to sensor i is denoted by \mathcal{N}_i . The task of the sensors is to estimate and track the state $y(t) \in \mathcal{Y} \cong \mathbb{R}^{d_y}$ of a phenomenon of interest (target), where \mathcal{Y} is a convex set. The target evolves according to the following *target motion model*:

$$y(t+1) = Fy(t) + \eta(t), \quad \eta(t) \sim \mathcal{N}(0, W), \quad (1)$$

where $\eta(t)$ is the process noise, whose values at any pair of times are independent. Sensor i , depending on its location x_i , can obtain a measurement $z_i(t)$ of the target state $y(t)$ at time t according to the following *sensor observation model*:

$$z_i(t) = H_i(x_i)y(t) + v_i(t, x_i), \quad v_i(t, x_i) \sim \mathcal{N}(0, V_i(x_i)), \quad (2)$$

where $v_i(t, x_i)$ is a sensor-state-dependent measurement noise that is independent at any pair of times and across different sensors. The measurement noise is independent of the target noise $\eta(t)$ as well. The signals, $z_i(t)$, observed by a single sensor, although potentially informative, do not reveal the target state completely, i.e. each sensor faces a local identification problem. We assume, however, that the target is observable if one has access to the signals received by all sensors.

To use the signals $z_i(t)$ for estimation, the sensors need to know their locations. However, it is common, especially in large networks, that they have only a rough estimate (prior). We suppose that each sensor has access to noisy relative measurements of the positions of its neighbors, which can be used to localize the sensors. In particular, at time t sensor i receives the following noisy relative configuration measurement from its neighbor j :

$$s_{ij}(t) = x_j - x_i + \epsilon_{ij}(t), \quad \epsilon_{ij}(t) \sim \mathcal{N}(0, \mathcal{E}_{ij}), \quad (3)$$

where $\epsilon_{ij}(t)$ is a measurement noise, which is independent at any pair of times and across sensor pairs. The relative measurement noises are independent of the target measurement and

motion noises too. Since there is translation ambiguity in the measurements (3) we assume that all sensors agree to localize themselves in the reference frame of sensor 1. The location estimates can then be used in place of the unknown sensor positions during the target estimation procedure. The joint localization and estimation problem is summarized below.

Problem (Joint Estimation and Localization). *The task of each sensor i is to construct estimators $\hat{x}_i(t)$ and $\hat{y}_i(t)$ of its own location x_i and of the target state y in a distributed manner, i.e. using information only from its neighbors and the measurements $\{s_{ij}(t) \mid j \in \mathcal{N}_i\}$ and $\{z_i(t)\}$.*

We use two scenarios to illustrate the results throughout the paper. The first is an environmental monitoring problem in which a sensor network of remote methane leak detectors (RMLD), based on tunable diode laser absorption spectroscopy [22], is deployed to estimate the methane concentration in a landfill. The methane field is assumed static ($F = I_{d_y}, W = 0$) and can be modeled by discretizing the environment into cells and representing the gas concentration with a Gaussian random field, $y \in \mathbb{R}^{d_y}$ (See Fig.5). It was verified experimentally in [22] that the RMLD sensors fit the linear model in (2).

Second, we consider tracking a swarm of mobile vehicles via a sensor network using range and bearing measurements (See Fig. 1). The position $(y_j^1, y_j^2) \in \mathbb{R}^2$ and velocity $(\dot{y}_j^1, \dot{y}_j^2) \in \mathbb{R}^2$ of the j -th target have discretized double integrator dynamics driven by Gaussian noise:

$$y_j(t+1) = \begin{bmatrix} I_2 & \tau I_2 \\ 0 & I_2 \end{bmatrix} y_j(t) + \eta_j(t), \quad W := q \begin{bmatrix} \frac{\tau^3}{3} I_2 & \frac{\tau^2}{2} I_2 \\ \frac{\tau^2}{2} I_2 & \tau I_2 \end{bmatrix},$$

where $y_j = [y_j^1, y_j^2, \dot{y}_j^1, \dot{y}_j^2]^T$ is the j -th target state, τ is the sampling period in *sec*, and q is a diffusion strength measured in $(\frac{m}{sec^2})^2 \frac{1}{Hz}$. Each sensor in the network takes noisy range and bearing measurements of each target's position:

$$z_{ij}(t) = \begin{bmatrix} \sqrt{(y_j^1 - x_i^1)^2 + (y_j^2 - x_i^2)^2} \\ \arctan((y_j^2 - x_i^2)/(y_j^1 - x_i^1)) \end{bmatrix} + v(t, x_i, y_j), \quad (4)$$

where $x_i := (x_i^1, x_i^2) \in \mathbb{R}^2$ is the sensor's location and the noise v grows linearly with the distance between the sensor and the target. The observation model is nonlinear in this case so we resort to linearization in order to apply our framework.

III. DISTRIBUTED TARGET TRACKING

Assuming for now that the sensors know their positions, we begin with the task of estimating and tracking the target state. We specialize the general parameter estimation scheme of Rahnama Rad and Tahbaz-Salehi [6] to linear Gaussian observation models such as (2). We show that the resulting distributed linear filter is mean-square consistent¹ when the target is stationary. This result is stronger than the weak consistency¹

¹A distributed estimator of a parameter y is *weakly consistent* if all estimates, $\hat{y}_i(t)$, converge in probability to y , i.e. $\lim_{t \rightarrow \infty} \mathbb{P}(\|\hat{y}_i(t) - y\| \geq \epsilon) = 0$ for any $\epsilon > 0$ and all i . It is *mean-square consistent* if all estimates converge in L^2 to y , i.e. $\lim_{t \rightarrow \infty} \mathbb{E}[\|\hat{y}_i(t) - y\|^2] = 0, \forall i$.

Fig. 1: A realization of the vehicle tracking scenario in which a sensor network with 40 nodes (grey) tracks 10 mobile vehicles via range and bearing measurements. The true and estimated vehicle trajectories are shown by solid curves and red dotted curves, respectively.

shown in the general non-Gaussian case in [6, Thm.1]. Suppose for now that the target is static, i.e. $y := y(0) = y(1) = \dots$. To introduce the estimation scheme from [6], suppose also that instead of the linear Gaussian measurements in (2), the sensor receive measurements, $z_i(t)$, drawn from a general distribution with conditional probability density function (pdf) $l_i(\cdot|y)$. As before, the signals observed by sensor i are iid over time and independent from the observations of all other sensors. In order to aggregate the information provided to it over time, each sensor i holds and updates a pdf $p_{i,t}$ over the target state space \mathcal{Y} . Consider the following distributed estimation algorithm:

$$p_{i,t+1}(y) = \xi_{i,t} l_i(z_i(t+1) | y) \prod_{j \in \mathcal{N}_i \cup \{i\}} (p_{j,t}(y))^{\kappa_{ij}} \quad (5)$$

$$\hat{y}_i(t) \in \arg \max_{y \in \mathcal{Y}} p_{i,t}(y)$$

where $\xi_{i,t}$ is a normalization constant ensuring that $p_{i,t+1}$ is a proper pdf and $\kappa_{ij} > 0$ are weights such that $\sum_{j \in \mathcal{N}_i \cup \{i\}} \kappa_{ij} = 1$. The update is the same as the standard Bayes rule except that sensor i does not just use its own prior but a *geometric average* of its neighbors' priors. Given a connected graph, the authors of [6] show that (5) is weakly consistent under broad assumptions on the observation models l_i .

Next, we specialize the estimator in (5) to the linear Gaussian measurement model in (2). Let $\mathcal{G}(\omega, \Omega)$ denote a Gaussian distribution (in information space) with mean $\Omega^{-1}\omega$ and covariance matrix Ω^{-1} . The quantities ω and Ω are conventionally called *information vector* and *information matrix*, respectively. Suppose that the pdfs $p_{i,t}$ of all sensors $i \in V$ at time t are that of Gaussian distributions $\mathcal{G}(\omega_{i,t}, \Omega_{i,t})$. We claim that the posteriors resulting from applying the update in (5) remain Gaussian.

Lemma 1 ([23, Thm.2]). *Let $Y_i \sim \mathcal{G}(\omega_i, \Omega_i)$ for $i = 1, \dots, n$ be a collection of random Gaussian vectors with associated weights κ_i . The weighted geometric mean, $\prod_{i=1}^n p_i^{\kappa_i}$, of their pdfs p_i is proportional to the pdf of a random vector with distribution $\mathcal{G}(\sum_{i=1}^n \kappa_i \omega_i, \sum_{i=1}^n \kappa_i \Omega_i)$.*

Lemma 2 ([23, Thm.2]). *Let $Y \sim \mathcal{G}(\omega, \Omega)$ and $\mathcal{V} \sim \mathcal{G}(0, V^{-1})$ be random vectors. Consider the linear transforma-*

Fig. 2: Initial and final (after 20 steps) node locations (red) estimated by the distributed localization algorithm on a randomly generated graph with 300 nodes (blue) and 1288 edges (blue dotted lines)

tion $Z = HY + \mathcal{V}$. The conditional distribution of $Y | Z = z$ is proportional to $\mathcal{G}(\omega + H^T V^{-1} z, \Omega + H^T V^{-1} H)$.

Lemma 1 states that if the sensor priors are Gaussian, then after the geometric averaging in (5), the average distribution will also be Gaussian and its information vector and information matrix will be weighted averages of the prior ones. Lemma 2 says that after applying Bayes rule the distribution remains Gaussian. Combining the two allows us to derive the following linear Gaussian version of the estimator in (5):

$$\omega_{i,t+1} = \sum_{j \in \mathcal{N}_i \cup \{i\}} \kappa_{ij} \omega_{j,t} + H_i^T V_i^{-1} z_i(t),$$

$$\Omega_{i,t+1} = \sum_{j \in \mathcal{N}_i \cup \{i\}} \kappa_{ij} \Omega_{j,t} + H_i^T V_i^{-1} H_i, \quad (6)$$

$$\hat{y}_i(t) := \Omega_{i,t}^{-1} \omega_{i,t},$$

where $H_i := H_i(x_i)$ and $V_i := V_i(x_i)$. We prove a strong result about the quality of the estimates in this linear Gaussian case.

Theorem 1. *Suppose that the communication graph G is connected and the matrix $[H_1^T \ \dots \ H_n^T]^T$ has rank d_y . Then, the estimates in (6) of all sensors converge in mean square to y , i.e. $\lim_{t \rightarrow \infty} \mathbb{E}[\|\hat{y}_i(t) - y\|_2^2] = 0$ for all i .*

The procedure in (6) can be extended to track dynamic targets as in (1) by adding a local prediction step, same as that of the Kalman filter, at each sensor. The resulting distributed linear filter is summarized in Alg. 1 and Thm. 1 guarantees its mean square consistency for static targets. Its performance on dynamic targets was studied in the vehicle tracking scenario introduced in Sec. II and the results are presented in Fig. 1 and Fig. 3.

IV. LOCALIZATION FROM RELATIVE MEASUREMENTS

Target tracking via the distributed estimator in Alg. 1 requires that the true sensor locations are known. As mentioned earlier this is typically not the case, especially for large sensor networks. This section describes a method for localization from relative measurements (3), whose strong convergence guarantees can be used to analyze the convergence of a joint

Fig. 3: Root mean squared error of the estimated vehicle positions and velocities obtained from averaging 50 simulated runs of the distributed linear estimator in the vehicle tracking scenario (Fig. 1). The error increases because as the vehicles move away from the sensor network the covariance of the measurement noise grows with the distance ($V(d_{ij}) = \text{diag}((0.07d_{ij} + 0.04)^2 \text{ m}^2, (d_{ij} + 2)^2 \text{ deg}^2)$ for $d_{ij} := \|x_i - y_j\|_2$). The errors of node 1 (blue) are lower because its location is known ($x_1 = 0$) and always close to the starting vehicle positions. The rest of the parameters were: $n = 40, q = 1.5, \tau = 0.2, \mathcal{E}_{ij} = 0.5I_2$.

Fig. 4: Root mean squared error of the localization estimates obtained from averaging 50 simulated runs of the distributed localization algorithm with randomly generated graphs with 300 nodes (e.g. Fig. 2), connectivity radius 10 m, and measurement covariances $\mathcal{E}_{ij} = I_2$

Algorithm 1 Distributed Linear Estimator

Input: Prior $(\omega_{i,t}, \Omega_{i,t})$, messages $(\omega_{j,t}, \Omega_{j,t}), \forall j \in \mathcal{N}_i$, and measurement $z_i(t)$

Output: $(\omega_{i,t+1}, \Omega_{i,t+1})$

Update Step: $\omega_{i,t+1} = \sum_{j \in \mathcal{N}_i \cup \{i\}} \kappa_{ij} \omega_{j,t} + H_i^T V_i^{-1} z_i(t)$

$\Omega_{i,t+1} = \sum_{j \in \mathcal{N}_i \cup \{i\}} \kappa_{ij} \Omega_{j,t} + H_i^T V_i^{-1} H_i$

$\hat{y}_i(t+1) = \Omega_{i,t+1}^{-1} \omega_{i,t+1}$

Prediction Step: $\Omega_{i,t+1} = (F \Omega_{i,t}^{-1} F^T + W)^{-1}$

$\omega_{i,t+1} = \Omega_{i,t+1} F \hat{y}_i(t+1)$

localization and estimation procedure. The relative measurements, received by all sensors at time t , can be written in matrix form as follows:

$$s(t) = (B \otimes I_d)^T x + \epsilon(t),$$

where $B \in \mathbb{R}^{n \times m}$ is the incidence matrix of the communication graph G . All sensors agree to localize relative to node 1 and know that $x_1 = 0$. Let $\tilde{B} \in \mathbb{R}^{(n-1) \times m}$ be the incidence matrix with the row corresponding to sensor 1 removed. Further, define $\mathcal{E} := \mathbb{E}[\epsilon(t)\epsilon(t)^T] = \text{diag}(\mathcal{E}_1, \dots, \mathcal{E}_m)$, where $\{\mathcal{E}_k\}$ is an enumeration of the noise covariances associated with the edges of G . Given t measurements, the least squares estimate of x leads to the classical Best Linear Unbiased Estimator (BLUE), given by:

$$\hat{x}(t) := (\tilde{B}\mathcal{E}^{-1}\tilde{B}^T)^{-1} \tilde{B}\mathcal{E}^{-1} \sum_{\tau=0}^{t-1} s(\tau), \quad (7)$$

where the inverse of $\tilde{B}\mathcal{E}^{-1}\tilde{B}^T$ exists as long as the graph G is connected [13]. The computation in (7) can be distributed via a Jacobi algorithm for solving a linear system as follows. Each sensor maintains an estimate $\hat{x}_i(t)$ of its own state at time t and a history of the averaged measurements, $\sigma_i(t) := \frac{1}{t+1} \sum_{\tau=0}^t \sum_{j \in \mathcal{N}_i} \mathcal{E}_{ij}^{-1} s_{ij}(\tau)$, received up to time t . Given prior estimates $(\hat{x}_i(t), \sigma_i(t))$, the update of the distributed Jacobi algorithm at sensor i is:

$$\begin{aligned} \hat{x}_i(t+1) &= \left(\sum_{j \in \mathcal{N}_i} \mathcal{E}_{ij}^{-1} \right)^{-1} \left(\sum_{j \in \mathcal{N}_i} \mathcal{E}_{ij}^{-1} \hat{x}_j(t) - \sigma_i(t) \right), \\ \sigma_i(t+1) &= \frac{1}{t+1} \left(t\sigma_i(t) + \sum_{j \in \mathcal{N}_i} \mathcal{E}_{ij}^{-1} s_{ij}(t) \right). \end{aligned} \quad (8)$$

Baroah and Hespanha [13], [14] show that, with a *single round* of measurements, the Jacobi algorithm provides an unbiased estimate of x . Here, we incorporate sequential measurements and prove a much stronger performance guarantee.

Theorem 2. *Suppose that the communication graph G is connected. Then, the estimates $\hat{x}_i(t)$ of the sensor configurations in (8) are mean-square and strongly consistent estimators of the true sensor states, i.e. for all i :*

$$\lim_{t \rightarrow \infty} \mathbb{E}[\|\hat{x}_i(t) - x_i\|_2^2] = 0, \quad \mathbb{P}\left(\lim_{t \rightarrow \infty} \|\hat{x}_i(t) - x_i\|_2 = 0\right) = 1$$

The performance of the distributed localization algorithm was analyzed on randomly generated graphs. An instance of the localization task is illustrated in Fig. 2, while the estimation error is shown in Fig. 4. The location priors were chosen from a normal distribution with standard deviation of 5 meters from the true node positions.

V. JOINT LOCALIZATION AND ESTIMATION

Having derived separate estimators for the sensor locations and the target state, we are ready to return to the original problem of joint localization and estimation. At time t , the location estimates $\{\hat{x}_i(t)\}$ in (8) can be used in the target estimator (6) instead of the true sensor positions. It is important to analyze the evolution of the coupled procedure because it is not clear that the convergence result in Thm. 1 will continue to hold. Define the *sensor acquisition matrix* $M_i(x) := H_i(x)^T V_i(x)^{-1} H_i(x)$. In an analogy with the centralized Kalman filter, the sensor acquisition matrix captures the amount of information added to the inverse of the covariance matrix during an update step of the Riccati map. From this point of view, it is natural to describe sensor properties in terms of the sensor acquisition matrix. A regularity assumption which stipulates that nearby sensing locations provide similar information gain is necessary.

Assumption. *The sensor acquisition matrices $M_i(x)$ are bounded continuous functions of x for all i .*

The following theorem ensures that the target state estimator retains its convergence properties when used jointly with the distributed localization procedure.

Theorem 3. *Let $\{\hat{x}_i(t)\}$ be strongly consistent estimators of the sensor configurations, i.e. $\hat{x}_i(t) \xrightarrow{a.s.} x_i, \forall i$. Suppose*

Fig. 5: Methane emission monitoring via a sensor network. The true (unknown) sensor locations (red nodes), the sensing range (red circle), and a typical realization of the methane field are shown on the left. The gas concentration varies from 0 to 800 parts per million (ppm) and the standard deviation of the measurements is 5 ppm. The root mean squared error of the location estimates and of the field estimates obtained from averaging 50 simulated runs of the joint localization and estimation algorithm with continuous sensor observation models are shown in the two middle plots (for $\mathcal{E}_{ij} = I_2$). In an additional experiment, the sensors were placed on the boundaries of the cells of the discretized field. As the observation model for each sensor was defined in terms of the proximal environment cells, this made the observation models discontinuous. The rightmost plot illustrates that the concentration estimation error does not vanish when discontinuities are present.

that the communication graph G is connected and the matrix $[H_1(x_1)^T \cdots H_n(x_n)^T]^T$ has rank d_y . Let $\delta > 0$ be arbitrary. If each sensor i updates its target estimate $(\omega_{i,t}, \Omega_{i,t})$ as follows:

$$\begin{aligned} \omega_{i,t+1} &= \sum_{j \in \mathcal{N}_i \cup \{i\}} \kappa_{ij} \omega_{j,t} + \hat{H}_{i,t}^T \hat{V}_{i,t}^{-1} z_i(t), \\ \Omega_{i,t+1} &= \sum_{j \in \mathcal{N}_i \cup \{i\}} \kappa_{ij} \Omega_{j,t} + \hat{H}_{i,t}^T \hat{V}_{i,t}^{-1} \hat{H}_{i,t}, \\ \hat{y}_i(t+1) &= (\Omega_{i,t+1} + (t+1)\delta I_d)^{-1} \omega_{i,t+1}, \end{aligned} \quad (9)$$

where $\hat{H}_{i,t} := H_i(\hat{x}_i(t))$ and $\hat{V}_{i,t} := V_i(\hat{x}_i(t))$, then the asymptotic mean square error of target estimates is $O(\delta^2)$:

$$\lim_{t \rightarrow \infty} \mathbb{E}[\|\hat{y}_i(t) - y\|_2^2] = \delta^2 y^T \left(\sum_{j=1}^n \pi_j M_j(x_j) + \delta I \right)^{-2} y,$$

for all i , where y is the true target state and x_j is the true position of sensor j .

According to Thm. 3, the combined procedure for estimating the sensor locations and the target state, specified by (8) and (9), has an arbitrarily small mean square error. Its performance was evaluated on the methane concentration estimation problem and the results are summarized in Fig. 5.

VI. CONCLUSION

This paper studied the problem of joint target tracking and node localization in sensor networks. A distributed linear estimator for tracking dynamic targets was derived. It was proven that the filter is mean square consistent when estimating static targets. Next, a distributed Jacobi algorithm was proposed for localization and its mean square and almost sure consistency were shown. Finally, the combined localization and target estimation procedure was shown to have arbitrarily small asymptotic estimation error. Future work will focus on more detailed simulations and real data experiments. Studying the relationship between our distributed linear estimator, the Kalman-Consensus filter [8], and the filter proposed by Khan et al. [9] is of great interest as well.

APPENDIX A: PROOF OF THEOREM 1

Define the following:

$$\begin{aligned} \omega_t &:= [\omega_{1t}^T \cdots \omega_{nt}^T]^T & \Omega_t &:= [\Omega_{1t}^T \cdots \Omega_{nt}^T]^T \\ M_i &:= H_i(x_i)^T V_i^{-1}(x_i) H_i(x_i) & M &:= [M_1^T \cdots M_n^T]^T \\ \zeta(t) &:= [H_1 V_1^{-T} v_1(t)^T \cdots H_n V_n^{-T} v_n(t)^T]^T. \end{aligned}$$

The update equations of the filter (6) in matrix form are:

$$\begin{aligned} \omega_{t+1} &= (\mathcal{K} \otimes I_{d_y}) \omega_t + M y + \zeta(t), \\ \Omega_{t+1} &= (\mathcal{K} \otimes I_{d_y}) \Omega_t + M, \end{aligned} \quad (10)$$

where $\mathcal{K} = [\kappa_{ij}]$ with $\kappa_{ij} = 0$ if $j \notin \mathcal{N}_i \cup \{i\}$ is a stochastic matrix. The solutions of the two linear dynamical systems are:

$$\begin{aligned} \omega_t &= (\mathcal{K} \otimes I_{d_y})^t \omega_0 + \sum_{\tau=0}^{t-1} (\mathcal{K} \otimes I_{d_y})^{t-1-\tau} (M y + \zeta(\tau)), \\ \Omega_t &= (\mathcal{K} \otimes I_{d_y})^t \Omega_0 + \sum_{\tau=0}^{t-1} (\mathcal{K} \otimes I_{d_y})^{t-1-\tau} M. \end{aligned}$$

Looking at the i -th components again, we have:

$$\begin{aligned} \frac{\omega_{it}}{t+1} &= \frac{1}{t+1} \sum_{j=1}^n [\mathcal{K}^t]_{ij} \omega_{j0} + \\ &\quad \frac{1}{t+1} \sum_{\tau=0}^{t-1} \sum_{j=1}^n [\mathcal{K}^{t-\tau-1}]_{ij} (M_j y + H_j^T V_j^{-1} v_j(\tau)), \\ \frac{\Omega_{it}}{t+1} &= \frac{1}{t+1} \sum_{j=1}^n [\mathcal{K}^t]_{ij} \Omega_{j0} + \frac{1}{t+1} \sum_{\tau=0}^{t-1} \sum_{j=1}^n [\mathcal{K}^{t-\tau-1}]_{ij} M_j. \end{aligned}$$

Define the following to simplify the notation:

$$\begin{aligned} g_{it} &:= \frac{1}{t+1} \sum_{j=1}^n [\mathcal{K}^t]_{ij} \omega_{j0}, \\ G_{it} &:= \frac{1}{t+1} \sum_{j=1}^n [\mathcal{K}^t]_{ij} \Omega_{j0}, \\ \phi_{it} &:= \frac{1}{t+1} \sum_{\tau=0}^{t-1} \sum_{j=1}^n [\mathcal{K}^{t-\tau-1}]_{ij} H_j^T V_j^{-1} v_j(\tau), \\ C_{it} &:= \frac{1}{t+1} \sum_{\tau=0}^{t-1} \sum_{j=1}^n [\mathcal{K}^{t-\tau-1}]_{ij} M_j, \\ b_{it} &:= g_{it} - G_{it} y, \quad B_{it} := \frac{1}{t+1} \Omega_{it}. \end{aligned} \quad (11)$$

With the shorthand notation:

$$\frac{\omega_{it}}{t+1} = g_{it} + \phi_{it} + C_{it}y, \quad B_{it} = \frac{\Omega_{it}}{t+1} = G_{it} + C_{it}, \quad (12)$$

where ϕ_{it} is the only random quantity. Its mean is zero because the measurement noise has mean zero, while its covariance is:

$$\begin{aligned} \mathbb{E}[\phi_{it}\phi_{it}^T] &= \frac{1}{(t+1)^2} \mathbb{E} \left[\left(\sum_{\tau=0}^{t-1} \sum_{j=1}^n [\mathcal{K}^{t-\tau-1}]_{ij} H_j^T V_j^{-1} v_j(\tau) \right) \right. \\ &\quad \times \left. \left(\sum_{s=0}^{t-1} \sum_{\eta=1}^n [\mathcal{K}^{t-s-1}]_{i\eta} H_\eta^T V_\eta^{-1} v_\eta(s) \right)^T \right] \\ &= \frac{1}{(t+1)^2} \sum_{j=1}^n \sum_{\tau=0}^{t-1} [\mathcal{K}^{t-\tau-1}]_{ij}^2 H_j^T V_j^{-1} \mathbb{E}[v_j(\tau)v_j(\tau)^T] V_j^{-1} H_j \\ &= \frac{1}{(t+1)^2} \sum_{j=1}^n \sum_{\tau=0}^{t-1} [\mathcal{K}^{t-\tau-1}]_{ij}^2 M_j \preceq \frac{1}{t+1} C_{it}, \end{aligned} \quad (13)$$

where the second equality uses the fact that $v_j(\tau)$ and $v_\eta(s)$ are independent unless the indices coincide, i.e. $\mathbb{E}v_j(\tau)v_\eta(s)^T = \delta_{\tau s}\delta_{j\eta}V_j$. The Löwner ordering inequality in the last step uses that $0 \leq [\mathcal{K}^{t-\tau-1}]_{ij} \leq 1$ and $M_j \succeq 0$.

Since G is connected, \mathcal{K} corresponds to the transition matrix of an aperiodic irreducible Markov chain with a unique stationary distribution π so that $\mathcal{K}^t \rightarrow \pi \mathbf{1}^T$ with $\pi_j > 0$. This implies that, as $t \rightarrow \infty$, the numerators of g_{it} and G_{it} remain bounded and therefore $g_{it} \rightarrow 0$ and $G_{it} \rightarrow 0$. Since Cesàro means preserve convergent sequences and their limits:

$$\frac{1}{t+1} \sum_{\tau=0}^{t-1} [\mathcal{K}^{t-\tau-1}]_{ij} \rightarrow \pi_j, \quad \forall i,$$

which implies that $C_{it} \rightarrow \sum_{j=1}^n \pi_j M_j$. The full-rank assumption on $[H_1^T \dots H_n^T]^T$ and $\pi_j > 0$ guarantee that $\sum_{j=1}^n \pi_j M_j$ is positive definite. Finally, consider the mean squared error:

$$\begin{aligned} &\mathbb{E}[(\hat{y}_i(t) - y)^T (\hat{y}_i(t) - y)] \\ &= \mathbb{E} \left\| \left(\frac{\Omega_{it}}{t+1} \right)^{-1} \frac{\omega_{it}}{t+1} - \left(\frac{\Omega_{it}}{t+1} \right)^{-1} \left(\frac{\Omega_{it}}{t+1} \right) y \right\|_2^2 \\ &= \mathbb{E} \| B_{it}^{-1} (g_{it} + C_{it}y + \phi_{it} - (G_{it} + C_{it})y) \|_2^2 \\ &= \mathbb{E} \| B_{it}^{-1} (b_{it} + \phi_{it}) \|_2^2 \\ &= \mathbb{E} \left[b_{it}^T B_{it}^{-T} B_{it}^{-1} b_{it} + 2b_{it}^T B_{it}^{-T} B_{it}^{-1} \phi_{it} + \phi_{it}^T B_{it}^{-T} B_{it}^{-1} \phi_{it} \right] \\ &\stackrel{(a)}{=} b_{it}^T B_{it}^{-T} B_{it}^{-1} b_{it} + \text{tr}(B_{it}^{-1} \mathbb{E}[\phi_{it}\phi_{it}^T] B_{it}^{-T}) \\ &\stackrel{(b)}{\leq} b_{it}^T B_{it}^{-T} B_{it}^{-1} b_{it} + \frac{1}{t+1} \text{tr}(B_{it}^{-1} C_{it} B_{it}^{-T}) \rightarrow 0, \end{aligned}$$

where (a) holds because the first term is deterministic, while the cross term contains $\mathbb{E}[\phi_{it}] = 0$. Inequality (b) follows from (13). In the final step, as shown before $B_{it}^{-1} \rightarrow (\sum_{j=1}^n \pi_j M_j)^{-1}$ and $C_{it} \rightarrow \sum_{j=1}^n \pi_j M_j \succ 0$ remain bounded, while $b_{it} \rightarrow 0$ and $1/(t+1) \rightarrow 0$. \square

APPENDIX B: PROOF OF THEOREM 2

Define the *generalized (matrix-weighted) degree matrix* $D \in \mathbb{R}^{nd \times nd}$ of graph G as the block-diagonal matrix with $D_{ii} := \sum_{j \in \mathcal{N}_i} \mathcal{E}_{ij}^{-1}$. Since $\mathcal{E}_{ij} \succ 0$ for all $\{i, j\} \in E$, the generalized degree matrix is positive definite, $D \succ 0$. Define also the *generalized adjacency matrix* $A \in \mathbb{R}^{nd \times nd}$ as follows:

$$A_{ij} := \begin{cases} \mathcal{E}_{ij}^{-1} & \text{if } \{i, j\} \in E, \\ 0 & \text{else.} \end{cases}$$

The *generalized Laplacian* and the *generalized signless Laplacian* of G are defined as $L := D - A$ and $|L| := D + A$, respectively. Further, let $R := (B \otimes I_d)^T \in \mathbb{R}^{md \times nd}$ and define the block-diagonal matrix $\mathcal{E} \in \mathbb{R}^{md \times md}$ with blocks \mathcal{E}_{ij} for $\{i, j\} \in E$. It is straightforward to verify that $L = R^T \mathcal{E}^{-1} R \succeq 0$ and $|L| = (|B| \otimes I_d) \mathcal{E}^{-1} (|B| \otimes I_d)^T \succeq 0$, where $|B| \in \mathbb{R}^{n \times m}$ is the signless incidence matrix of G . Let $\tilde{B} \in \mathbb{R}^{(n-1) \times m}$ and $\tilde{R} \in \mathbb{R}^{md \times (n-1)d}$ be the matrices resulting from removing the row corresponding to sensor 1 from B . Similarly, let $\tilde{D}, \tilde{A}, \tilde{L}, |\tilde{L}| \in \mathbb{R}^{(n-1)d \times (n-1)d}$ denote the generalized degree, adjacency, Laplacian, and signless Laplacian matrices with the row and column corresponding to sensor 1 removed. Thm. 2.2.1 in [14] shows that $\tilde{L} \succ 0$ provided that G is connected. The same approach can be used to show that $|\tilde{L}| \succ 0$. Let $\tilde{x} \in \mathbb{R}^{(n-1)d}$ be the locations of sensors 2, \dots , n in the reference frame of sensor 1 and $\hat{x}(t) \in \mathbb{R}^{(n-1)d}$ be their estimates at time t obtained from (8). The update in (8) can be written in matrix form as follows:

$$\tilde{D}\hat{x}(t+1) = \tilde{A}\hat{x}(t) + \tilde{R}^T \mathcal{E}^{-1} \left(\tilde{R}\tilde{x} + \frac{1}{t+1} \sum_{\tau=0}^t \epsilon(\tau) \right). \quad (14)$$

Define the estimation error at time t as $e(t) := \tilde{x} - \hat{x}(t)$ and let $u(t) := \frac{1}{t+1} \sum_{\tau=0}^t \epsilon(\tau)$. The dynamics of the error state can be obtained from (14):

$$\begin{aligned} e(t+1) &= \tilde{x} - \tilde{D}^{-1} \tilde{A} \hat{x}(t) - \tilde{D}^{-1} \tilde{L} \tilde{x} - \tilde{D}^{-1} \tilde{R}^T \mathcal{E}^{-1} u(t) \\ &= \tilde{x} - \tilde{D}^{-1} \tilde{A} \hat{x}(t) - \tilde{D}^{-1} (\tilde{D} - \tilde{A}) \tilde{x} - \tilde{D}^{-1} \tilde{R}^T \mathcal{E}^{-1} u(t) \\ &= \tilde{D}^{-1} \tilde{A} e(t) - \tilde{D}^{-1} \tilde{R}^T \mathcal{E}^{-1} u(t). \end{aligned}$$

The error dynamics are governed by a stochastic linear time-invariant system, whose internal stability depends on the eigenvalues of $\tilde{D}^{-1} \tilde{A}$. To show that the error dynamics are stable, we resort to the following lemma.

Lemma 3 ([24, Lemma 4.2]). *Let $L = D - A \in \mathbb{C}^{n \times n}$ be such that $D + D^* \succ 0$ and $L_\theta = D + D^* - (e^{i\theta} A + e^{-i\theta} A^*) \succ 0$ for all $\theta \in \mathbb{R}$. Then $\rho(D^{-1} A) < 1$.*

Consider $\tilde{L}_\theta := 2(\tilde{D} - \cos(\theta)\tilde{A})$. If $\cos \theta = 0$, then $\tilde{L}_\theta = 2\tilde{D} \succ 0$. If $\cos \theta \in (0, 1]$, then $\tilde{L}_\theta \succeq 2\cos \theta \tilde{L} \succ 0$. Finally, if $\cos \theta \in [-1, 0)$, then $\tilde{L}_\theta \succeq 2|\cos \theta| |\tilde{L}| \succ 0$. Therefore, $\rho(\tilde{D}^{-1} \tilde{A}) < 1$. The proof of the theorem is completed by the following lemma with $F := \tilde{D}^{-1} \tilde{A}$ and $G := -\tilde{D}^{-1} \tilde{R}^T \mathcal{E}^{-1}$.

Lemma 4. *Consider the discrete-time stochastic linear time-invariant system, $e(t+1) = F e(t) + G \frac{1}{t+1} \sum_{\tau=0}^t \epsilon(\tau)$, driven*

by Gaussian noise $\epsilon(\tau) \sim \mathcal{N}(0, \mathcal{E})$, which is independent at any pair of times. If the spectral radius of F satisfies $\rho(F) < 1$, then $e(t) \xrightarrow{a.s., L^2} 0$.

Proof. By the strong law of large numbers [25, Thm.2.4.1], $u(t) := \frac{1}{t+1} \sum_{\tau=0}^t \epsilon(\tau)$ converges to 0 almost surely. Let Ω be the set with measure 1 on which $u(t)$ converges so that for any $\gamma > 0$, $\exists T \in \mathbb{N}$ such that $\forall t \geq T$, $\|u(t)\| \leq \gamma$. For realizations in Ω , the solution with initial time T is:

$$e(t) = F^{t-T} e(T) + \sum_{\tau=T}^{t-1} F^{t-\tau-1} G u(\tau).$$

Then, $\|e(t)\| \leq \|F^{t-T} e(T)\| + \sum_{\tau=T}^{t-1} \|F^{t-\tau-1}\| \|G\| \gamma$. Taking the limit of t and using that F is stable, we have

$$\lim_{t \rightarrow \infty} \|e(t)\| \leq \left(\sum_{\tau=0}^{\infty} \|F^\tau\| \right) \|G\| \gamma.$$

Since $\rho(F) < 1$, the system is internally (uniformly) exponentially stable, which is equivalent to $\sum_{\tau=0}^{\infty} \|F^\tau\| \leq \beta$ for some finite constant β [26, Ch.22]. Thus, $\lim_{t \rightarrow \infty} \|e(t)\| \leq \beta \|G\| \gamma$, which can be made arbitrarily small by choice of γ . We conclude that $e(t) \rightarrow 0$ on Ω and consequently $e(t) \xrightarrow{a.s.} 0$.

Next, we show convergence in L^2 . First, consider the propagation of the cross term $C(t) := (t+1) \mathbb{E} e(t) u(t)^T$. Note that $\mathbb{E} u(t) = 0$ and $\mathbb{E} u(t) u(t)^T = \frac{\mathcal{E}}{t+1}$. Using the fact that $\epsilon(t+1)$ is independent of $e(t)$ and $u(t)$ we have

$$\begin{aligned} C(t+1) &= \mathbb{E}(F e(t) + G u(t)) ((t+1) u(t) + \epsilon(t+1))^T \\ &= F C(t) + (t+1) G \mathbb{E} u(t) u(t)^T = F C(t) + G \mathcal{E}. \end{aligned}$$

The solution of the above linear time-invariant system is:

$$C(t) = F^t C(0) + \sum_{\tau=0}^{t-1} F^{t-\tau-1} G \mathcal{E}$$

and since F is stable: $\lim_{t \rightarrow \infty} \mathbb{E} e(t) u(t)^T = \lim_{t \rightarrow \infty} \frac{1}{t+1} \sum_{\tau=0}^{t-1} F^\tau G \mathcal{E} = 0$.

Now, consider the second moment of the error:

$$\begin{aligned} \Sigma(t+1) &:= \mathbb{E} e(t+1) e(t+1)^T = \\ &F \Sigma(t) F^T + F \left(\mathbb{E} e(t) u(t)^T \right) G^T + G \left(\mathbb{E} u(t) e(t)^T \right) F^T + \frac{1}{t+1} G \mathcal{E} G^T \\ &= F \Sigma(t) F^T + Q(t), \end{aligned}$$

where $Q(t) := \frac{1}{t+1} \left(F C(t) G^T + G C(t)^T F^T + G \mathcal{E} G^T \right)$. As shown above $Q(t) \rightarrow 0$ as $t \rightarrow \infty$, i.e. for any $\delta > 0$, $\exists T' \in \mathbb{N}$ such that $\forall t \geq T'$, $\|Q(t)\| \leq \delta$. With initial time T' , for $t \geq T'$:

$$\begin{aligned} \Sigma(t) &= F^{t-T'} \Sigma(T') (F^T)^{t-T'} + \sum_{\tau=T'}^{t-1} F^{t-\tau-1} Q(\tau) (F^T)^{t-\tau-1} \\ \|\Sigma(t)\| &\leq \|F^{t-T'}\|^2 \|\Sigma(T')\| + \sum_{\tau=0}^{t-T'-1} \|F^\tau\|^2 \delta \\ &\leq \alpha^2 \mu^{2(t-T')} + \delta \alpha^2 \sum_{\tau=0}^{t-T'-1} \mu^{2\tau}, \end{aligned}$$

where the existence of the constants $\alpha > 0$ and $0 \leq \mu < 1$ is guaranteed by the stability of F . We conclude that $\lim_{t \rightarrow \infty} \|\Sigma(t)\| \leq \frac{\delta \alpha^2}{1-\mu^2}$, which can be made arbitrarily small by choice of δ . In other words, $e(t) \xrightarrow{L^2} 0$. \square

APPENDIX C: PROOF OF THEOREM 3

We use the same notation and approach as in the proof of Thm 1, except that now the terms $H_i, V_i, M_i, M, \zeta(t), \phi_{it}, C_{it}, B_{it}$ are time-varying and stochastic because they depend on the location estimates $\hat{x}_i(t)$. To emphasize this, we denote them by $\hat{H}_{it}, \hat{V}_{it}, \hat{M}_{it}, \hat{M}_t, \hat{\zeta}(t), \hat{\phi}_{it}, \hat{C}_{it}, \hat{B}_{it}$, where for example $\hat{M}_{it} := M_i(\hat{x}_i(t))$. The same linear systems (10) describe the evolutions of ω_t and Ω_t except that they are stochastic now and (12) becomes:

$$\frac{\omega_{it}}{t+1} = g_{it} + \hat{C}_{it} y + \hat{\phi}_{it}, \quad \hat{B}_{it} := \frac{\Omega_{it}}{t+1} = G_{it} + \hat{C}_{it}.$$

We still have that $\mathcal{K}^t \rightarrow \pi \mathbf{1}^T$ with $\pi_j > 0$. Also, g_{it}, G_{it} , and b_{it} are still deterministic and converge to zero as $t \rightarrow \infty$. The following observations are necessary to conclude that \hat{C}_{it} still converges to $\sum_{j=1}^n \pi_j M_j$.

Lemma 5. *If $\hat{x}_i(t) \xrightarrow{a.s.} x_i$, then $\hat{M}_{it} \xrightarrow{a.s., L^2} M_i$.*

Proof. Almost sure convergence follows from the continuity of $M_i(\cdot)$ and the continuous mapping theorem [25, Thm.3.2.4]. L^2 -convergence follows from the boundedness of $M_i(\cdot)$ and the dominated convergence theorem [25, Thm.1.6.7]. \square

Lemma 6. *If $a_t \rightarrow a$ and $b_t \rightarrow b$, then $\frac{1}{t} \sum_{\tau=0}^{t-1} a_{t-\tau} b_\tau \rightarrow ab$.*

Proof. The convergence of a_t implies its boundedness, $|a_t| \leq q < \infty$. Then, notice $ab = \frac{1}{t} \sum_{\tau=0}^{t-1} ab$ and

$$\begin{aligned} \left| \frac{1}{t} \sum_{\tau=0}^{t-1} a_{t-\tau} b_\tau - ab \right| &= \left| \frac{1}{t} \sum_{\tau=0}^{t-1} (a_{t-\tau} (b_\tau - b) + (a_{t-\tau} - a) b) \right| \\ &\leq \left| \frac{1}{t} \sum_{\tau=0}^{t-1} a_{t-\tau} (b_\tau - b) \right| + \left| \frac{1}{t} \sum_{\tau=0}^{t-1} (a_{t-\tau} - a) b \right| \\ &\leq \left| q \left(\frac{1}{t} \sum_{\tau=0}^{t-1} b_\tau - b \right) \right| + \left| \left(\frac{1}{t} \sum_{\tau=1}^t a_\tau - a \right) b \right|, \end{aligned}$$

where both terms converge to zero since Cesàro means preserve convergent sequences and their limits. \square

Combining Lemma 5, $[\mathcal{K}^t]_{ij} \rightarrow \pi_j$, and Lemma 6, we have:

$$\frac{1}{t+1} \sum_{\tau=0}^{t-1} [\mathcal{K}^{t-\tau-1}]_{ij} \hat{M}_{j\tau} \xrightarrow{a.s.} [\pi \mathbf{1}^T]_{ij} M_j = \pi_j M_j.$$

Moreover, $0 \leq [\mathcal{K}^t]_{ij} \leq 1$ and the boundedness of \hat{M}_{jt} imply, by the bounded convergence theorem [25, Thm.1.6.7], that the sequence above converges in L^2 as well:

$$\hat{C}_{it} \xrightarrow{a.s., L^2} \sum_{j=1}^n \pi_j M_j \succ 0. \quad (15)$$

In turn, (15) guarantees that:

$$\hat{B}_{it}^{-2} = (G_{it} + \hat{C}_{it})^{-2} \xrightarrow{a.s.} \left(\sum_{j=1}^n \pi_j M_j \right)^{-2} \quad (16)$$

but is not enough to ensure that $\mathbb{E}[\widehat{B}_{it}^{-2}]$ remains bounded as $t \rightarrow \infty$. The parameter $\delta > 0$ is needed to guarantee the boundedness. In particular, define $\widehat{B}_{it}(\delta) := \widehat{B}_{it} + \delta I_{d_y}$. Then

$$\widehat{B}_{it}(\delta)^{-2} = (G_{it} + \widehat{C}_{it} + \delta I_{d_y})^{-2} \prec \frac{1}{\delta^2} I_{d_y}$$

and by the bounded convergence theorem and (16):

$$\widehat{B}_{it}(\delta)^{-2} \xrightarrow{a.s., L^1} \left(\sum_{j=1}^n \pi_j M_j + \delta I_{d_y} \right)^{-2}, \quad (17)$$

so that $\lim_{t \rightarrow \infty} \mathbb{E}[\widehat{B}_{it}(\delta)^{-2}] < \infty$. From (15) and the boundedness of $\widehat{B}_{it}(\delta)^{-1}$ and \widehat{C}_{it} , we also have:

$$\begin{aligned} & \widehat{B}_{it}(\delta)^{-1} \widehat{C}_{it} \widehat{B}_{it}(\delta)^{-T} \xrightarrow{a.s., L^2} \\ & \left(\sum_{j=1}^n \pi_j M_j + \delta I_{d_y} \right)^{-1} \left(\sum_{j=1}^n \pi_j M_j \right) \left(\sum_{j=1}^n \pi_j M_j + \delta I_{d_y} \right)^{-T}. \end{aligned} \quad (18)$$

Since \widehat{H}_{it} and \widehat{V}_{it} depend solely on $\widehat{x}_i(t)$, they are independent of $v_i(t)$. Because $\mathbb{E}[v_j(\tau)] = 0$, $\mathbb{E}[\widehat{H}_{j\tau}^T \widehat{V}_{j\tau}^{-1} v_j(\tau)] = 0$ and as before $\mathbb{E}[\widehat{\phi}_{it}] = 0$. Since $\widehat{B}_{it}(\delta)$ is independent of $v_i(t)$ as well, $\mathbb{E}[\widehat{B}_{it}(\delta)^{-2} \widehat{\phi}_{it}] = 0$ and a result equivalent to (13) holds:

$$\begin{aligned} & \mathbb{E}[\widehat{B}_{it}(\delta)^{-1} \widehat{\phi}_{it} \widehat{\phi}_{it}^T \widehat{B}_{it}(\delta)^{-T}] \\ & = \mathbb{E} \left[\widehat{B}_{it}(\delta)^{-1} \left(\frac{1}{(t+1)^2} \sum_{j=1}^n \sum_{\tau=0}^{t-1} [\mathcal{K}^{t-\tau-1}]_{ij}^2 \widehat{M}_{j\tau} \right) \widehat{B}_{it}(\delta)^{-T} \right] \\ & \prec \frac{1}{t+1} \mathbb{E}[\widehat{B}_{it}(\delta)^{-1} \widehat{C}_{it} \widehat{B}_{it}(\delta)^{-T}]. \end{aligned} \quad (19)$$

Finally, consider the mean squared error:

$$\begin{aligned} \mathbb{E}[\|\widehat{y}_i(t) - y\|_2^2] & = \mathbb{E} \left\| \widehat{B}_{it}(\delta)^{-1} \frac{\omega_{it}}{t+1} - \widehat{B}_{it}(\delta)^{-1} \widehat{B}_{it}(\delta) y \right\|_2^2 \\ & = \mathbb{E} \left\| \widehat{B}_{it}(\delta)^{-1} \left(g_{it} + \widehat{C}_{it} y + \widehat{\phi}_{it} - (G_{it} + \widehat{C}_{it} + \delta I_{d_y}) y \right) \right\|_2^2 \\ & = \mathbb{E} \|\widehat{B}_{it}(\delta)^{-1} (b_{it} + \widehat{\phi}_{it} + \delta y)\|_2^2 \\ & = \mathbb{E} \left[b_{it}^T \widehat{B}_{it}(\delta)^{-2} b_{it} + \widehat{\phi}_{it}^T \widehat{B}_{it}(\delta)^{-2} \widehat{\phi}_{it} + \delta^2 y^T \widehat{B}_{it}(\delta)^{-2} y \right. \\ & \quad \left. + 2b_{it}^T \widehat{B}_{it}(\delta)^{-2} \widehat{\phi}_{it} + 2\delta y^T \widehat{B}_{it}(\delta)^{-2} \widehat{\phi}_{it} + 2\delta b_{it}^T \widehat{B}_{it}(\delta)^{-2} y \right] \\ & = b_{it}^T \mathbb{E}[\widehat{B}_{it}(\delta)^{-2}] b_{it} + \text{tr}(\mathbb{E}[\widehat{B}_{it}(\delta)^{-1} \widehat{\phi}_{it} \widehat{\phi}_{it}^T \widehat{B}_{it}(\delta)^{-T}]) \\ & \quad + \delta^2 y^T \mathbb{E}[\widehat{B}_{it}(\delta)^{-2}] y + 2\delta b_{it}^T \mathbb{E}[\widehat{B}_{it}(\delta)^{-2}] y \\ & \stackrel{(19)}{\leq} b_{it}^T \mathbb{E}[\widehat{B}_{it}(\delta)^{-2}] b_{it} + 2\delta b_{it}^T \mathbb{E}[\widehat{B}_{it}(\delta)^{-2}] y + \delta^2 y^T \mathbb{E}[\widehat{B}_{it}(\delta)^{-2}] y \\ & \quad + \frac{1}{t+1} \text{tr} \left(\mathbb{E} \left[\widehat{B}_{it}(\delta)^{-1} \widehat{C}_{it} \widehat{B}_{it}(\delta)^{-T} \right] \right) \\ & \rightarrow \delta^2 y^T \left(\sum_{j=1}^n \pi_j M_j + \delta I_{d_y} \right)^{-2} y. \end{aligned}$$

In the final step, the first two terms go to zero because $b_{it} \rightarrow 0$ and $\lim_t \mathbb{E}[\widehat{B}_{it}(\delta)^{-2}] < \infty$ from (17), the third term converges in view of (17) again, while the last term goes to zero because the trace is bounded in the limit in view of (18). \square
