Receding Horizon Temporal Logic Planning
Tichakorn Wongpiromsarn, Ufuk Topcu, and Richard M. Murray

Abstract—We present a methodology for automatic synthesis of embedded control software that incorporates a class of linear temporal logic (LTL) specifications sufficient to describe a wide range of properties including safety, stability, progress, obligation, response and guarantee. To alleviate the associated computational complexity of LTL synthesis, we propose a receding horizon framework that effectively reduces the synthesis problem into a set of smaller problems. The proposed control structure consists of a goal generator, a trajectory planner, and a continuous controller. The goal generator reduces the trajectory generation problem into a sequence of smaller problems of short horizon while preserving the desired system-level temporal properties. Subsequently, in each iteration, the trajectory planner solves the corresponding short-horizon problem with the currently observed state as the initial state and generates a feasible trajectory to be implemented by the continuous controller. Based on the simulation property, we show that the composition of the goal generator, trajectory planner and continuous controller and the corresponding receding horizon framework guarantee the correctness of the system with respect to its specification regardless of the environment in which the system operates. In addition, we present a response mechanism to handle failures that may occur due to a mismatch between the actual system and its model. The effectiveness of the proposed technique is demonstrated through an example of an autonomous vehicle navigating an urban environment. This example also illustrates that the system is not only robust with respect to exogenous disturbances but is also capable of properly handling violation of the environment assumption that is explicitly stated as part of the system specification.

Index Terms—Autonomous systems, control architecture, linear temporal logic, receding horizon control.

I. INTRODUCTION

Design and verification of modern engineered systems with a tight link between computational and physical elements have become increasingly complex due to the interleaving between the high-level logics and the low-level dynamics. Consider, for example, an autonomous driving problem, particularly the 2007 DARPA Urban Challenge. In this competition, the competing vehicles had to navigate, in a fully autonomous manner, through a partially known urban-like environment populated with static and dynamic obstacles and perform different tasks such as road and off-road driving, parking and visiting certain areas while obeying traffic rules. For the vehicles to successfully complete the race, they need to be capable of negotiating an intersection, handling changes in the environment or operating condition and replanning in response to such changes. Hence, the high-level logic that governs the behavior of the vehicles needs to be properly integrated with the low-level controller that regulates the physical hardware.

A schematic of the hierarchical protocol stack implemented in Team Caltech’s entry in the challenge is shown in Fig. 1. The stack comprises multiple software modules that are responsible for reasoning at different levels of abstraction [1], [2], [3]. Path Follower, for example, computes control signals based on the continuous model of the vehicle such that the vehicle closely follows the path generated by Path Planner. Mission Planner generates a route to complete the mission based only on the discrete model of the connectivity between different road segments. Finally, Traffic Planner, implemented as a set of finite state machines, determines how the vehicle should navigate this route incorporating the traffic rules. This paper particularly focuses on the traffic planner and path follower layers of such protocol stacks.

Protocol stacks on autonomous vehicles constitute an example of a broader class of systems, namely embedded control systems that incorporate continuous and discrete decision making and interact with the (potentially dynamic and a priori unknown) environment. These systems are typically very complex, yet a lot of them are still designed and implemented in an ad-hoc manner. Even though the individual components may be formally verified, the whole system is typically verified only through simulations and tests. Hence, there is no formal guarantee that the system would work as desired. In fact, a design bug in Team Caltech’s entry in the Urban Challenge related to a mismatch in the abstraction of the physical system used at different levels of the hierarchy had never been discovered in thousands of hours of our extensive simulations and over three hundred miles of field testing [4]. In addition, once the bug was uncovered, it was difficult to modify and verify the design due to the complexity of the system and the lack of sufficient time. Although it might be impractical to simplify such a system, part of the complexity could be avoided if the system had been designed in a systematic way.

Motivated by the difficulty of modifying and verifying complex embedded control systems, in this paper, we investigate the following control protocol synthesis problem.

Problem Description: Given a model for the system and its specification expressed in a formal language, synthesize a control protocol that, by construction, ensures that the system satisfies its specification for all valid environment behaviors.

In particular, we consider discrete-time linear time-invariant system and use linear temporal logic [5], [6], [7] as the specification language. Environment refers to the factors over which the system has no control such as obstacles, weather condition, software and hardware faults and failures, etc. We assume that the system respects its model and ensure that an execution described by the model, rather than the actual execution of the system, satisfies the specification. (Checking that the model accurately describes the actual system is a validation problem which is not in the scope of the paper.)
A Solution Approach and Associated Issues: A common approach to the above synthesis problem is to construct a finite transition system that serves as an abstract model of the physical system (which typically has infinitely many states) [8], [9], [10], [11], [12], [13], [14], [15], [16]. Then based on this abstract model, synthesize a strategy, represented by a finite state automaton, satisfying the specification. This leads to a hierarchical, two-layer design with a discrete planner computing a discrete plan based on the abstract model and a continuous controller computing control signal based on the physical model to continuously implement the discrete plan. Simulations/bisimulations [17] provide a proof that the continuous execution preserves the correctness of the discrete plan. We describe this hierarchical approach in detail in Section IV.

One of the main challenges of this hierarchical approach is in the abstraction of continuous, infinite-state systems into equivalent (in the simulation sense) finite state models. Several abstraction methods have been proposed based on a fixed abstraction. For example, a continuous-time, time-invariant model was considered in [9], [10] and [11] for special cases of fully actuated ($\dot{s}(t) = u(t)$), kinematic ($\dot{s}(t) = A(s(t))u(t)$) and piecewise affine (PWA) dynamics, respectively. A discrete-time, time-invariant model was considered in [14] and [12] for special cases of PWA and controllable linear systems, respectively. Reference [13] deals with more general dynamics by relaxing the bisimulation requirement and using the notion of approximate simulation [18]. More recently, a sampling-based method has been proposed for $\mu$-calculus specifications [8].

Another issue is the computational complexity in the synthesis of finite state automata from a temporal logic specification, especially in the presence of the dynamic and a priori unknown environment. Piterman et al. [19] treated this problem as a two-player game between the system and the environment and proposed an algorithm for the synthesis of a finite state automaton that satisfies its specification for any environment behavior. Although for a certain class of properties, known as Generalized Reactivity[1], such an automaton can be computed in polynomial time, for practical problems, the rapid increase in computational complexity is still a limiting factor.

Contributions of the paper: This paper concerns both the abstraction and the computational complexity issues. First, in Section V, we propose an approach to automatically compute a finite state abstraction for a discrete-time linear time-invariant system, taking into account exogenous disturbances. Our approach differs from those presented in [9], [10], [11], [12], [13], [14] as we explicitly take into account the presence of exogenous disturbances. Although exogenous disturbances have been considered in [20], the state space is partitioned based on a fixed geometric shape (e.g., a hypercube of fixed size). Hence, the size the of resulting state space may be unnecessarily large. To alleviate this shortcoming, we start with a predicate-based partition and refine it based on the reachability relation to polytopic regions of different size and shape. This allows us to control the size of the state space and identify the set of initial states starting from which a control law that ensures the satisfaction of the desired properties cannot be found.

Second, in Section VI, we propose a receding horizon framework for executing finite state automata while ensuring system correctness with respect to a given linear temporal logic specification. This framework essentially reduces the synthesis problem into a set of smaller problems of shorter horizon. It relies on the partial order relation among the discrete states. The partial order plays a role similar to the contraction constraints [21], [22], which practically induce an order in the state space, in receding horizon control literature. The implementation of the receding horizon framework, presented in Section VII, leads to the decomposition of the discrete planner into a goal generator and a trajectory planner. The goal generator reduces the synthesis problem to a sequence of short-horizon problems while preserving the desired system-level temporal properties. Subsequently, in each iteration, the trajectory planner solves the corresponding short-horizon problem with the currently observed state as the initial state and generates a feasible trajectory to be implemented by the continuous controller.

Finally, we present a response mechanism that potentially increases the robustness of the system with respect to a mismatch between the actual system and its model and violation of the environment assumptions. The proposed technique is demonstrated through an example of an autonomous vehicle navigating an urban-like environment. This example also illustrates that the resulting hierarchical control structure is not only robust with respect to exogenous disturbances but also capable of handling violation of the environment assumptions.

Preliminary versions of this work have partially appeared in [14], [15], [16].

II. PRELIMINARIES

We use linear temporal logic (LTL) to specify properties of systems. In this section, we first give formal definitions of terminology and notations used throughout the paper. Then, based on these definitions, we briefly describe LTL and some important classes of LTL formulas.

Definition 1. A system consists of a set $V$ of variables. The
domain of $V$, denoted by $\text{dom}(V)$, is the set of valuations of $V$. A state of the system is an element $v \in \text{dom}(V)$.

We describe an execution of a system by an infinite sequence of its states. Specifically, for a discrete-time system, its execution $\sigma$ can be written as $\sigma = v_0v_1v_2\ldots$ where $v_i \in \text{dom}(V)$ is the state of the system at time $t$.

**Definition 2.** A finite transition system is a tuple $\mathcal{T} := (V, \mathcal{V}_0, \rightarrow)$ where $V$ is a finite set of states, $\mathcal{V}_0 \subseteq V$ is a set of inital states, and $\rightarrow \subseteq V \times V$ is a transition relation. Given states $v_i, v_j \in \mathcal{V}$, we write $v_i \rightarrow v_j$ if there is a transition from $v_i$ to $v_j$ in $\mathcal{T}$.

In this paper, we use $v$ to represent a state of a finite transition system and $v$ to represent a state of a general, possibly non-finite state system.

**Definition 3.** A partially ordered set $(V, \leq)$ consists of a set $V$ and a binary relation $\leq$ over the set $V$ satisfying the following properties: for any $v_1, v_2, v_3 \in V$, (a) $v_1 \leq v_1$; (b) if $v_1 \leq v_2$ and $v_2 \leq v_1$, then $v_1 = v_2$; and (c) if $v_1 \leq v_2$ and $v_2 \leq v_3$, then $v_1 \leq v_3$.

**Definition 4.** An atomic proposition is a statement on system variables $v$ that has a unique truth value (True or False) for a given value of $v$. Let $v \in \text{dom}(V)$ be a state of the system and $p$ be an atomic proposition. We write $v \models p$ if $p$ is True at the state $v$. Otherwise, we write $v \not\models p$.

LTL is a powerful specification language for unambiguously and concisely expressing a wide range of properties of systems [5], [6], [7]. It is built up from (a) a set of atomic propositions, (b) the logic connectives: negation ($\neg$), disjunction ($\lor$), conjunction ($\land$) and material implication ($\implies$), and (c) the temporal modal operators: next ($\Box$), always ($\Diamond$), eventually ($\Diamond^*$) and until ($U$). An LTL formula is defined inductively as follows: (1) any atomic proposition $p$ is an LTL formula; and (2) given LTL formulas $\varphi$ and $\psi$, $\neg \varphi$, $\varphi \lor \psi$, $\varphi \land \psi$, $\Box \varphi$ and $\varphi U \psi$ are also LTL formulas. Other operators can be defined as follows: $\varphi \land \psi \equiv \neg (\neg \varphi \lor \neg \psi)$, $\varphi \implies \psi \equiv \neg \varphi \lor \psi$, $\Diamond \varphi \equiv \Box \varphi$ and $\Diamond^* \varphi \equiv \neg \Diamond^* \neg \varphi$. A propositional formula is one that does not include temporal operators. Given a set of LTL formulas $\varphi_1, \ldots, \varphi_n$, their Boolean combination is an LTL formula formed by joining $\varphi_1, \ldots, \varphi_n$ with logic connectives.

**Semantics of LTL:** An LTL formula is interpreted over an infinite sequence of states. Given an execution $\sigma = v_0v_1v_2\ldots$ and an LTL formula $\varphi$, we write $v_i \models \varphi$ if $\varphi$ holds at position $i \geq 0$ of $\sigma$. The semantics of LTL is defined inductively as follows: (a) For an atomic proposition $p$, $v_i \models p$ if and only if $i \geq 0$; (b) $v_i \models \neg \varphi$ iff $v_i \not\models \varphi$; (c) $v_i \models \varphi \lor \psi$ iff $v_i \not\models \varphi$ or $v_i \not\models \psi$; (d) $v_i \models \varphi \land \psi$ iff $v_{i+1} \models \varphi$; and (e) $v_i \models \varphi U \psi$ iff there exists $j \geq i$ such that $v_j \models \psi$ and $\forall k \in [i,j), v_k \models \varphi$.

Based on this definition, $\Diamond \varphi$ holds at position $v_i$ iff $\varphi$ holds at the next state $v_{i+1}$, $\Box \varphi$ holds at position $i$ iff $\varphi$ holds at every position in $\sigma$ starting at position $i$, and $\Box \varphi$ holds at position $i$ iff $\varphi$ holds at some position $j \geq i$ in $\sigma$.

**Definition 5.** An execution $\sigma = v_0v_1v_2\ldots$ satisfies $\varphi$, denoted by $\sigma \models \varphi$, if $v_0 \not\models \varphi$.

**Definition 6.** Let $\Sigma$ be the set of all executions of a system. The system is said to be correct with respect to the specification $\varphi$, written $\Sigma \models \varphi$, if all its executions satisfy $\varphi$, that is, $(\Sigma \models \varphi)$ if $(\forall \sigma \in \Sigma \Rightarrow (\sigma \models \varphi))$.

**Remark 1.** Properties typically studied in the control and hybrid systems domains are safety (usually in the form of constraints on the system state) and stability (i.e., convergence to an equilibrium or a desired state). However, these properties are not rich enough to describe certain desired properties of, for example, an autonomous vehicle such as staying in the travel lane unless there is an obstacle blocking the lane, and visiting a certain area infinitely often. In Section VIII, we show how such properties can be easily expressed in LTL. Examples of widely-used LTL formulas include safety, guarantee, obligation, progress, response and stability.

### III. Problem Formulation

We consider a system that comprises the physical component, which we refer to as the plant, and the (potentially dynamic and a priori unknown) environment in which the plant operates. Specifically, we define the system $S$ and the specification $\varphi$ as follows.

**System:** Consider a system $S$ with a set $V = S \cup E$ of variables where $S$ and $E$ are disjoint sets that represent, respectively, the set of plant variables that are regulated by the control protocol and the set of environment variables whose values may change arbitrarily throughout an execution. The domain of $V$ is given by $\text{dom}(V) = \text{dom}(S) \times \text{dom}(E)$ and a state of the system can be written as $v = (s, e)$ where $s \in \text{dom}(S) \subseteq \mathbb{R}^n$ and $e \in \text{dom}(E)$. We call $s$ the controlled state and $e$ the environment state.

The controlled state evolves according to the following discrete-time linear time-invariant state space model: for $t \in \{0, 1, 2, \ldots\}$,

$$
\begin{align*}
\dot{s}[t + 1] &= As[t] + Bs[u[t] + B_d d[t]], \\
\dot{u}[t] &\in U, d[t] \in D, s[0] \in \text{dom}(S),
\end{align*}
$$

where $U \subseteq \mathbb{R}^m$ is the set of admissible control inputs, $D \subseteq \mathbb{R}^p$ is the set of exogenous disturbances and $s[t], u[t]$ and $d[t]$ are the controlled state, control signal and disturbance at time $t$.

**Example 1.** Take, for example, a scenario where a robot needs to navigate an environment populated with (potentially dynamic) obstacles and explore certain areas of interest. $S$ typically includes the state (e.g. position and velocity) of the robot while $E$ typically includes the positions of obstacles (which are generally not known a priori and may change over time). The evolution of the controlled state (i.e., the state of the robot) is governed by its equations of motion.

**System Specification:** We assume that the specification $\varphi$ is of the form

$$
\varphi = (\varphi_{\text{init}} \land \varphi_e) \implies \varphi_s,
$$

where $\varphi_{\text{init}}$ specifies system’s initial conditions, $\varphi_e$ describes the knowledge about the allowable environment behavior and the desired behavior of the systems in encoded in $\varphi_s$.

Let $\Pi$ be a finite set of atomic propositions of variables from $V$. Each of the atomic propositions in $\Pi$ essentially captures the states of interest. We assume that the desired behavior $\varphi_s$ is an LTL specification built from $\Pi$ and can be expressed as a conjunction of safety, guarantee, obligation, progress, response and stability properties as follows

$$
\varphi_s = \bigwedge_{j \in J_1} \Box \neg \psi_{s,j} \land \bigwedge_{j \in J_2} \Diamond \neg \psi_{s,j} \land \bigwedge_{i \in I_1} \neg \Box \psi_{s,i} \land \bigwedge_{i \in I_2} \neg \Diamond \psi_{s,i},
$$

where $J_1, \ldots, J_6$ are finite sets and for any $i$ and $j$, $\psi_{s,i}$ and $\psi_{s,j}$ are propositional formulas of variables from $V$ that are built from $\Pi$.

Furthermore, we assume that $\varphi_{\text{init}}$ is a propositional formula built from $\Pi$ and $\varphi_e$ can be expressed as a conjunction of safety and justice requirements as follows

$$
\varphi_e = \bigwedge_{i \in I_1} \Box p_{f,i} \land \bigwedge_{i \in I_2} \Diamond p_{e,i},
$$

where $p_{f,i}$ and $p_{e,i}$ are propositional formulas built from $\Pi$ and only contain variables from $E$. Note that we restrict $\varphi_s$ and $\varphi_e$ to be of the form (3) and (4), respectively, for the clarity of presentation. Our framework only requires that the specification (2) can be reduced to the form of equation (6), presented later.

Example 2. Consider the robot motion planning problem described in Example 1. Suppose the workspace of the robot is partitioned into cells $C_1, \ldots, C_M$ and the robot needs to visit cells $C_1$ and $C_2$ infinitely often. We assume that one of the cells $C_1, C_2$ may be occupied by an obstacle at any given time. In addition, this obstacle-occupied cell may change arbitrarily throughout an execution but infinitely often, $C_1$ and $C_2$ are not occupied. Let $s$ and $o$ represent the position of the robot and the obstacle, respectively. In this case,

$$
\varphi_s = \Box \psi_e \land \Box \psi_{f,i} = \bigwedge_{i \in I_1} \Box \psi_{f,i} \land \bigwedge_{i \in I_2} \Diamond \psi_{f,i},
$$

Assuming that initially, the robot does not occupy the same cell as the obstacle,

$$
\varphi_{\text{init}} = ((o \in C_1) \land (s \notin C_1)) \land \ldots \land ((o \in C_M) \land (s \notin C_M)),
$$

Finally, the assumption on the environment can be expressed as $\varphi_e = \Box \psi_e \land \Diamond \psi_{f,i} = \bigwedge_{i \in I_1} \Box \psi_{f,i} \land \bigwedge_{i \in I_2} \Diamond \psi_{f,i}.$

Control Protocol Synthesis Problem: Given a system $S$ and specification $\varphi$, synthesize a control protocol that generates a sequence of control signals $u[0], u[1], \ldots \in U$ to the plant to ensure that starting from any initial condition, $\varphi$ is satisfied for any sequence of exogenous disturbances $d[0], d[1], \ldots \in D$ and any sequence of environment states.

Note that the control objective is to ensure that the specification $\varphi$ is satisfied for any initial condition and environment, including those that violate the assumptions $\varphi_{\text{init}}$ and $\varphi_e$. However, according to (2), $\varphi$ holds in any execution where $\varphi_{\text{init}}$ or $\varphi_e$ is violated. Hence, the desired behavior $\varphi_s$ only needs to be ensured when $\varphi_{\text{init}}$ and $\varphi_e$ are satisfied.

IV. HIERARCHICAL APPROACH

We take a hierarchical approach to solve the Control Protocol Synthesis Problem stated in Section III. First, we construct a finite transition system $D$ that serves as an abstract model of $S$. The problem is then decomposed into (a) synthesizing a discrete planner that computes a discrete plan satisfying the specification $\varphi$ based on the abstract, finite-state model $D$, and (b) designing a continuous controller that implements the discrete plan. The success of this abstraction-based approach thus relies on the following two critical steps:

(a) an abstraction of an infinite-state system into an equivalent (in the simulation sense) finite state model such that any discrete plan generated by the discrete planner can be implemented (i.e., simulated); see, for example, [23] for the exact definition of simulation) by the continuous controller, provided that the evolution of the controlled state satisfies (1), and
(b) synthesis of a discrete planner (i.e., a strategy), represented by a finite state automaton, that ensures the correctness of the discrete plan.

In Section V, we present an approach for step (a), assuming that the physical system is modeled as described in Section III. For step (b) and ensure the system correctness for any initial condition and environment behavior, we apply the two-player game approach presented in [19] to synthesize a discrete planner as in [9], [14]. We refer the reader to [19] and references therein for a detailed discussion. In summary, consider a class of LTL formulas of the form

$$
\psi_{\text{init}} \land \Box \psi_e \land \bigwedge_{i \in I_1} \Diamond \psi_{f,i} \implies \bigwedge_{i \in I_s} \Box \psi_{s,i} \land \bigwedge_{i \in I_g} \Diamond \psi_{g,i},
$$

known as Generalized Reactivity[1] (GR[1]) formulas. Here, $\psi_{\text{init}}, \psi_{f,i}$, and $\psi_{g,i}$ are propositional formulas of variables from $V$; $\psi_e$ is a Boolean combination of propositional formulas of variables from $V$ and expressions of the form $\Box \psi_e$ where $\psi_e$ is a propositional formula of variables from $E$ that describes the assumptions on the transitions of environment states; $\psi_{s,i}$ is a Boolean combination of propositional formulas of variables from $V$ and expressions of the form $\Box \psi_{s,i}$ where $\psi_{s,i}$ is a propositional formula of variables from $V$ that describes the constraints on the transitions of controlled states. The approach presented in [19] allows checking the realizability of this class of specifications and synthesizing the corresponding finite state automaton to be performed in $O(|V|^3)$ time where $|V|$ is the number of states of the finite state abstraction $D$.

Proposition 1. A specification of the form (2)–(4) can be reduced to a subclass of GR[1] formula of the form

$$
\psi_{\text{init}} \land \Box \psi_e \land \bigwedge_{i \in I_f} \Diamond \psi_{f,i},
$$

where $\psi_{\text{init}}, \psi_{f,i}$ and $\psi_{g,i}$ are as defined above and $\psi_e$ and $\psi_{f,i}$ are propositional formulas of variables from $E$.

Throughout the paper, we refer to the left hand side and the right hand side of (6) as the “assumption” part and the “guarantee” part, respectively. The proof of Proposition 1 is
based on the fact that all safety, guarantee, obligation, and response properties are special cases of progress formulas \(\Box \Diamond \phi\), provided that \(\phi\) is allowed to be a past formula [5]. Hence, these properties can be reduced to the guarantee part of (6) by introducing auxiliary Boolean variables. For example, the guarantee property \(\Box \Diamond p_{2,j}\) can be reduced to the guarantee part of (6) by introducing an auxiliary Boolean variable \(x\), initialized to \(p_{2,j}\). The formula \(\Box \Diamond p_{2,j}\) can then be equivalently expressed as a conjunction of \(\Box((x \lor p_{2,j}) \implies \Box x)\), \(\Box((\neg x \lor p_{2,j}) \implies \Box(\neg x))\) and \(\Box \Diamond x\). Obligation and response properties can be reduced to the guarantee part of (6) using a similar idea. In addition, the stability property \(\Box \Box \Diamond p_{0,j}\) can be reduced to the guarantee part of (6) by introducing an auxiliary Boolean variable \(y\), initialized to False. The formula \(\Box \Box \Diamond p_{0,j}\) can then be equivalently expressed as a conjunction of \(\Box( y \implies p_{0,j})\), \(\Box(y \implies \Box y)\), \(\Box(\neg y \implies (\Box y \lor \Box(\neg y)))\) and \(\Box \Diamond y\). Note that these reductions lead to equivalent specifications. However, for the case of stability \(\Box \Box \Diamond p_{0,j}\), the reduction may lead to an unrealizable specification even though the original specification is realizable. Roughly speaking, this is because the auxiliary Boolean variable \(y\) needs to make clairvoyant (prophecy), non-deterministic decisions. For other properties, the realizability remains the same after the reduction since the synthesis algorithm [19] is capable of handling past formulas. The detail of this discussion is beyond the scope of this paper and we refer the reader to [19] for more detailed discussion on the synthesis of GR[1] specification.

In Section VI, we describe a receding horizon framework that incorporates LTL specification of the form (6) in order to reduce the computational complexity of the synthesis problem. Its implementation and a response mechanism that enables the system to handle certain failures and continue to exhibit a correct behavior are presented in Section VII.

V. COMPUTING FINITE STATE ABSTRACTION

To construct a finite transition system \(\mathcal{D}\) from the physical model \(\mathcal{S}\), we first partition \(\text{dom}(\mathcal{S})\) and \(\text{dom}(\mathcal{E})\) into finite sets \(\mathcal{S}\) and \(\mathcal{E}\), respectively, of equivalence classes or cells such that the partition is proposition preserving [17]. Roughly speaking, a partition is said to be proposition preserving if for any atomic proposition \(\pi \in \Pi\) and any states \(v_1\) and \(v_2\) that belong to the same cell in the partition, \(v_1\) satisfies \(\pi\) iff \(v_2\) also satisfies \(\pi\). We denote the resulting discrete domain of the system by \(\mathcal{V} = \mathcal{S} \times \mathcal{E}\). We call \(\nu \in \text{dom}(\mathcal{V})\) a continuous state and \(\nu \in \mathcal{V}\) a discrete state of the system. For a discrete state \(\nu \in \mathcal{V}\), we say that \(\nu\) satisfies an atomic proposition \(\pi \in \Pi\), denoted by \(\nu \models \pi\), iff there exists a continuous state \(\nu\) contained in the cell labeled by \(\nu\) such that \(\nu\) satisfies \(\pi\). (Due to the proposition preserving property of the partition, the existence of such a state \(\nu \models \pi\) implies that all the continuous states contained in the cell labeled by \(\nu\) satisfies \(\pi\).) Given an infinite sequence of discrete states \(\sigma_d = \nu_0 \nu_1 \nu_2 \ldots\) and LTL formula \(\varphi\) built from \(\Pi\), we write \(\nu_i \Vdash \varphi\) if \(\varphi\) holds at position \(i \geq 0\) of \(\sigma_d\). With these definitions, the semantics of LTL for a sequence of discrete states can be derived from the general semantics of LTL.

Next, we need to determine the transition relations \(\rightarrow\) of \(\mathcal{D}\). In Section V-A, we use a variant of the notion of reachability that is sufficient to guarantee that if a discrete controlled state \(\varsigma_j\) is reachable from \(\varsigma_i\), the transition from \(\varsigma_i\) to \(\varsigma_j\) can be continuously implemented or simulated by a continuous controller. A computational scheme that provides a sufficient condition for reachability between two discrete controlled states and subsequently refines the state space partition is also presented in Sections V-B and V-C.

A. Finite-Time Reachability

Let \(\mathcal{S} = \{\varsigma_1, \varsigma_2, \ldots, \varsigma_l\}\) be a set of discrete controlled states. We define a map \(\mathcal{T}_s : \text{dom}(\mathcal{S}) \rightarrow \mathcal{S}\) that sends a continuous controlled state to a discrete controlled state of its equivalence class. That is, \(\mathcal{T}_s^{-1}(\varsigma_i) \subseteq \text{dom}(\mathcal{S})\) is the set of all the continuous controlled states contained in the cell labeled by \(\varsigma_i\) and \(\{\mathcal{T}_s^{-1}(\varsigma_1), \ldots, \mathcal{T}_s^{-1}(\varsigma_l)\}\) is the partition of \(\text{dom}(\mathcal{S})\).

Definition 7. A discrete state \(\varsigma_j\) is reachable from a discrete state \(\varsigma_i\), written \(\varsigma_i \leadsto \varsigma_j\), only if starting from any point \(s(0) \in \mathcal{T}_s^{-1}(\varsigma_i)\), there exists a horizon length \(N \in \{0, 1, \ldots\}\) such that for any sequence of exogenous disturbances \(d[0], d[1], \ldots, d[N - 1] \in \mathcal{D}\), there exists a sequence of control signals \(u[0], u[1], \ldots, u[N - 1] \in U\) that takes the system (1) to a point \(s[N] \in \mathcal{T}_s^{-1}(\varsigma_j)\) satisfying the constraint \(s[t] \in \mathcal{T}_s^{-1}(\varsigma_i) \cup \mathcal{T}_s^{-1}(\varsigma_j)\) for all \(t \in \{0, \ldots, N\}\). We write \(\varsigma_i \not\leadsto \varsigma_j\) if \(\varsigma_j\) is not reachable from \(\varsigma_i\).

In general, for two discrete states \(\varsigma_i\) and \(\varsigma_j\), verifying the reachability relation \(\varsigma_i \leadsto \varsigma_j\) is hard because it requires searching for a proper horizon length \(N\). Therefore, we consider the restricted case where the horizon length is fixed and given and \(U, D\) and \(\mathcal{T}_s^{-1}(\varsigma_i), i \in \{1, \ldots, l\}\) are polyhedral sets. Our approach relies on solving the following problem.

Reachability Problem: Given an initial continuous controlled state \(s(0) \in \mathbb{R}^n\), discrete controlled states \(\varsigma_i, \varsigma_j \in \mathcal{S}\), the set of admissible control inputs \(U \subseteq \mathbb{R}^m\), the set of exogenous disturbances \(D \subseteq \mathbb{R}^p\), the matrices \(A, B_u\) and \(B_d\) as in (1), a horizon length \(N \geq 0\), determine a sequence of control signals \(u[0], u[1], \ldots, u[N - 1] \in \mathbb{R}^m\) such that for all \(t \in \{0, \ldots, N - 1\}\) and \(d[t] \in D\),

\[
s[t + 1] = As[t] + B_u u[t] + B_dd[t],
\]

\[
s[t] \in \mathcal{T}_s^{-1}(\varsigma_i), u[t] \in U, s[N] \in \mathcal{T}_s^{-1}(\varsigma_j)
\]

(7)

If the above Reachability Problem is feasible, a solution \(u[0], \ldots, u[N - 1]\) can be computed by formulating a constrained optimal control problem, which can be solved using off-the-shelf software such as MPT [24], YALMIP [25] or NTG [26].

B. Verifying the Reachability Relation

Given two discrete controlled states \(\varsigma_i, \varsigma_j \in \mathcal{S}\), to determine whether \(\varsigma_i \leadsto \varsigma_j\), we essentially have to verify that \(\mathcal{T}_s^{-1}(\varsigma_j) \subseteq \mathcal{S}_0\) where \(\mathcal{S}_0\) is the set of \(s(0)\) starting from which the Reachability Problem defined in Section V-A is feasible. In this section, we describe how \(\mathcal{S}_0\) can be computed using an idea from constrained robust optimal control [27].
We assume that \( U, D \) and \( T^{-1}(s_i), i \in \{1, \ldots, l\} \) are polyhedral sets, i.e., there exist matrices \( L_1, L_2 \) and \( L_3 \) and vectors \( M_1, M_2, M_3 \) such that \( T^{-1}(s_i) = \{ s \in \mathbb{R}^n \mid L_1 s \leq M_1 \} \), \( U = \{ u \in \mathbb{R}^m \mid L_2 u \leq M_2 \} \) and \( T^{-1}(s) = \{ s \in \mathbb{R}^n \mid L_3 s \leq M_3 \} \). Then, by substituting

\[
s[t] = A^t s[0] + \sum_{k=0}^{n} (A^k B_u u[t-1-k] + A^k B_d d[t-1-k])
\]

and replacing \( s[t] \in T^{-1}(s_i), u[t] \in U \) and \( s[N] \in T^{-1}(s_j) \) with \( L_1 s[t] \leq M_1, L_2 u[t] \leq M_2 \) and \( L_3 s[N] \leq M_3 \), respectively, in (7), it can be easily checked that (7) can be rewritten in the form \( L [s[0], u^t] \leq M - G d, \forall d \in D^N \) and \( S_0 \) be the projection of \( P \) onto its first \( n \) coordinates, i.e.,

\[
S_0 = \left\{ s \in \mathbb{R}^n \mid \exists \hat{u} \in \mathbb{R}^m \text{ s.t. } L \left[ \begin{array}{c} s \\ \hat{u} \end{array} \right] \leq M - G d, \forall d \in D^N \right\}.
\]

Then, the Reachability Problem defined in Section V-A is feasible if there exist \( s[0] \in S_0 \).

Using Proposition 2, the problem of computing \( S_0 \) such that the Reachability Problem is feasible for any \( s[0] \in S_0 \) is reduced to computing a projection of the intersection of finite sets.

### C. State Space Discretization and Correctness of the System

In general, given the predicate-based partition of \( dom(S) \) and \( i, j \in \{1, \ldots, n\} \), the reachability relation between \( s_i \) and \( s_j \) may not be established through the set \( S_0 \) of \( s[0] \) starting from which the Reachability Problem defined in Section V-A is feasible. (Due to the constraints on \( u \) and a specific choice of the finite horizon \( N \), \( T^{-1}(s_i) \) is not necessarily covered by \( S_0 \).) To partially alleviate this limitation, we refine the partition based on the reachability relation to increase the number of valid discrete state transitions of \( D \). The underlying idea is that starting with an arbitrary pair of \( s_i \) and \( s_j \), we determine the set \( S_0 \) of feasible \( s[0] \) for the Reachability Problem. Then, we partition \( T^{-1}(s_i) \) into \( T^{-1}(s_i) \cap S_0 \), labeled by \( s_i,1 \), and \( T^{-1}(s_j) \setminus S_0 \), labeled by \( s_i,2 \), and obtain the following reachability relations:

\[
s_i1 \rightarrow s_j \text{ and } s_i2 \rightarrow s_j.
\]

This process is continued until some pre-specified termination criteria are met.

Table I shows the pseudo-code of the algorithm where a prescribed lower bound \( Vol_{min} \) on the volume of each cell in the new partition is used as a termination criterion. The algorithm terminates when no cell can be partitioned such that the volumes of the two resulting new cells are both greater than \( Vol_{min} \). Larger \( Vol_{min} \) causes the algorithm to terminate sooner. Other termination criteria such as the maximum number of iterations can be used as well. Note that the point at which the algorithm terminates affects the reachability between discrete controlled states of the new partition and as a result, affects the realizability of the specification. Generally, a coarse partition may render the specification unrealizable whereas a fine partition increases the computational cost. A way to decide when to terminate the algorithm is to start with a coarse partition and keep refining it until the specification is realizable or the computational resources are exhausted.

It can be shown that the resulting partition of \( dom(S) \), after applying the discretization algorithm, contains at most \( N_{max} = vol(dom(S))/Vol_{min} \) cells. Hence, the number of iterations does not exceed \( N_{max} \). We denote the set of all the discrete controlled states corresponding to the resulting partition of \( dom(S) \) by \( S' \). Since the partition obtained from the proposed algorithm is a refined partition of \( \{ T^{-1}(S_1), \ldots, T^{-1}(S_n) \} \) and \( V = S \times E \) is proposition preserving, it is trivial to show that \( V' = S' \times E \) is also proposition preserving. For simplicity of notation, we call \( S' \) as \( S \) and \( V' \) as \( V \) for the rest of the paper.

We define the finite transition system \( D \) that serves as the abstract model of \( S \) as: (a) \( V = S \times E \) is the set of states of \( D \), and (b) \( \nu_1 \rightarrow \nu_2 \) where \( \nu_1, \nu_2 \in V \), \( \nu_1 = (s_i, \epsilon_i) \) and \( \nu_2 = (s_j, \epsilon_j) \) only if \( s_i \rightarrow s_j \). Using the abstract model \( D \), a discrete planner that guarantees the satisfaction of \( \varphi \) while ensuring that the discrete plans are restricted to those satisfying the reachability relations can be automatically constructed using the digital design synthesis tool [19].

From the stutter invariant property of \( \varphi \) [28], the formulation of the Reachability Problem and the proposition preserving property of \( V \), it is straightforward to prove the correctness of the hierarchical approach.

**Proposition 3.** Let \( \sigma \) be an infinite sequence of discrete states of \( D \) where for each natural number \( k, \nu_k \rightarrow \nu_{k+1} \), \( \nu_k = (s_k, \epsilon_k), s_k \in S \) is the discrete controlled state and \( \epsilon_k \in E \) is the discrete environment state. If \( \sigma \) satisfies \( \varphi \), then by applying a sequence of control signals, each corresponding to a solution of the Reachability Problem with \( s_i = s_k \) and \( s_j = s_{k+1} \), the infinite sequence of continuous states \( \sigma = \nu_0, \nu_2, \ldots \) satisfies \( \varphi \).
Remark 2. In verifying the reachability relation, we consider the restricted case where the horizon length \( N \) is fixed and given. In addition, the discretization algorithm terminates when a user-defined termination criterion is met. This may lead to a conservative result, i.e., cell \( c_j \) (or part of it) may be reachable from cell \( c_i \) according to Definition 7 even though the discretization algorithm declares that \( c_i \not\sim c_j \). Hence, the resulting partition may render the specification unrealizable even though there exists a provably correct control protocol.

VI. RECEDING HORIZON FRAMEWORK

The main limitation of the synthesis of finite state automata from their LTL specifications [19] is the state explosion problem. In the worst case, the resulting automaton may contain all the possible states of the system. For example, if the system has \( |V| \) variables, each can take any value in \( \{1, \ldots, M\} \), then there may be as many as \( M^{|V|} \) nodes in the automaton. This type of computational complexity limits the application of synthesis to relatively small problems.

Similar computational complexity is also encountered in the area of constrained optimal control. In the controls domain, an effective and well-established technique to address this issue is to design and implement control strategies in a receding horizon manner, i.e., optimize over a shorter horizon, starting from the currently observed state, implement the initial control action, move the horizon one step ahead, and re-optimize. This approach reduces the computational complexity by essentially solving a sequence of smaller optimization problems, each with a specific initial condition (as opposed to optimizing with any initial condition in traditional optimal control). Under certain conditions, receding horizon control strategies are known to lead to closed-loop stability [26], [22], [29]. See, e.g., [30] for a detailed discussion on constrained optimal control, including finite horizon optimal control and receding horizon control.

To reduce computational complexity in the synthesis of finite state automata, we apply an idea similar to the traditional receding horizon control. First, we observe that in many applications, it is not necessary to plan for the whole execution, taking into account all the possible behaviors of the environment since a state that is very far from the current state of the system typically does not affect the near future plan. Consider, for example, the robot motion planning problem described in Example 2. Suppose \( C_1 \) or \( C_2 \) is very far away from the initial position of the robot. Under certain conditions, it may be sufficient to only plan out an execution for only a short segment ahead and implement it in a receding horizon fashion, i.e., re-compute the plan as the robot moves, starting from the currently observed state (rather than from all initial conditions satisfying \( \psi_{init} \) as the original specification (2) suggests). In this section, we present a sufficient condition and a receding horizon strategy that allows the synthesis to be performed on a smaller domain; thus, substantially reduces the number of states (or nodes) of the automaton while still ensuring the system correctness with respect to the LTL specification (2).

We assume that a finite state abstraction \( \mathcal{D} \) of the system \( \mathcal{S} \) has been constructed using, for example, the discretization algorithm presented in Section V-C. Let \( \mathcal{V} \) be the finite set of states of \( \mathcal{D} \). We consider a specification of the form (6) since, from Proposition 1, the specification (2) can be reduced to this form. Let \( \Phi \) be a propositional formula of variables from \( V \) such that \( \psi_{init} \implies \Phi \) is a tautology, i.e., any state \( \nu \in \mathcal{V} \) that satisfies \( \psi_{init} \) also satisfies \( \Phi \). For each progress property \( \square \psi \), \( i \in I_g \), suppose there exists a collection of subsets \( \mathcal{W}_i, \ldots, \mathcal{W}_p \) of \( \mathcal{V} \) such that

\[
\begin{align*}
(a) & \quad \mathcal{W}_0 \cup \mathcal{W}_1 \cup \ldots \cup \mathcal{W}_p = \mathcal{V}, \\
(b) & \quad \psi_{\nu,i} \text{ is satisfied for any } \nu \in \mathcal{W}_0, \text{ i.e., } \mathcal{W}_0 \text{ is the set of the states that constitute the progress of the system, and} \\
(c) & \quad \mathcal{P}^i := \{(W_0^i, \ldots, W_p^i) : \psi_{\nu,i} \} \text{ is a partially ordered set} \\
& \quad \text{defined such that } \mathcal{W}_0^i \prec \psi_{\nu,i}, \mathcal{W}_j^i, \forall j \neq i.
\end{align*}
\]

Define a map \( \mathcal{F}^i : \{W_0^i, \ldots, W_p^i\} \to \{W_0^i, \ldots, W_p^i\} \) such that \( \mathcal{F}^i(W_j^i) = W_{j-1}^i, j \geq 2 \) and \( \mathcal{F}(W_j^i) = W_0^i \) and \( \mathcal{F}(W_0^i) = \mathcal{W}_0^i \). Suppose \( \nu_1 \) is the initial state of the system. The key idea of the receding horizon framework, as described later, is to plan from \( \nu_1 \) to a state in \( \mathcal{F}(W_1^i) = \mathcal{W}_2^i \), rather than planning from the initial state \( \nu_1 \) to the goal state \( \nu_{10} \) in one shot, taking into account all the possible behaviors of the environment. Once a state in \( \mathcal{W}_1^i \), i.e., \( \nu_0 \) or \( \nu_0 \) is reached, we then replan from that state to a state in \( \mathcal{F}(W_1^i) = \mathcal{W}_1^i \). We repeat this process until \( \nu_{10} \) is reached. Under certain sufficient conditions presented later, this strategy ensures the correctness of the overall execution of the system.

Formally, with the above definitions of \( \Phi, \mathcal{W}_0^i, \ldots, \mathcal{W}_p^i \) and \( \mathcal{F}^i \), we define a short-horizon specification \( \Psi_j^i \) associated with \( \mathcal{W}_j^i \) for each \( i \in I_g \) and \( j \in \{0, \ldots, p\} \) as

\[
\Psi_j^i \overset{\triangleq}{=} (\mathcal{W}_0^i \land \Phi) \land \square \psi_{e,i} \land \land_{k=1}^i \square \land_{s,k} \psi_{s,k} \\
= \land_{k=1}^i \square \land_{s,k} \psi_{s,k} \land \land_{k=1}^i \square \land_{s,k} \psi_{s,k}
\]

where \( \nu \) is the state of the system and \( \psi_{e,i}, \psi_{s,k} \) and \( \psi_{s,k} \) are defined as in (6). An automaton \( A_j^i \) satisfying \( \Psi_j^i \) defines a strategy for going from a state \( \nu_1 \in \mathcal{W}_1^i \) to a state \( \nu_2 \in \mathcal{F}(\mathcal{W}_1^i) \) while satisfying the safety requirements \( \land_{k=1}^i \square \land_{s,k} \psi_{s,k} \) and maintaining the invariant \( \Phi \). The roles of \( \mathcal{P}^i, \mathcal{F}^i \) and \( \Phi \) are discussed later in Section VI-A.

Receding Horizon Strategy: For each \( i \in I_g \) and \( j \in \{0, \ldots, p\} \), construct an automaton \( A_j^i \) satisfying \( \Psi_j^i \). Let \( I_g = \{i_1, \ldots, i_n\} \) and define a corresponding ordered set \( (i_1, \ldots, i_n) \). This order only affects the sequence of progress.
properties \(\psi_{g,i}, \ldots, \psi_{g,i_n}\) that the system tries to satisfy and can be picked arbitrarily without affecting the correctness of the strategy.

1. Determine the index \(j_1\) such that the current state \(\nu_0 \in W_{j_1}^i\). If \(j_1 \neq 0\), then execute automaton \(A_{j_1}^i\) until the system reaches a state \(\nu_1 \in W_{k}^i\) where \(W_{k}^i \preceq \psi_{g,i}, W_{j}^i\). Note that since the union of \(W_{j_1}^i, \ldots, W_{j_p}^i\) is the set \(\nu\) of all the states, given any \(\rho_0, \rho_1, \rho_2 \in \nu\), there exist \(j_1, k \in \{0, \ldots, p\}\) such that \(\rho_0 \in W_{j_1}^i\) and \(\rho_1 \in W_{k}^i\).

2. If the current state \(\nu_1 \notin W_{0}^i\), switch to automaton \(A_{j_2}^i\) where the index \(j_2\) is chosen such that the current state \(\nu_1 \in W_{j_2}^i\). Execute \(A_{j_2}^i\) until the system reaches a state that is smaller in the partial order \(\mathcal{P}^{j_2}\). Repeat this process until a state \(\nu_2 \in W_{0}^i\) is reached.

3. Switch to automaton \(A_{j_2}^i\) where the index \(j_2\) is chosen such that the current state \(\nu_2 \in W_{j_2}^i\). Repeat step (2) with \(i_1\) replaced by \(i_2\) for the partial order \(\mathcal{P}^{j_2}\) until a state \(\nu_3 \in W_{0}^i\) is reached. Repeat this process with \(i_2\) replaced by \(i_3, i_4, \ldots, i_n\) until a state \(\nu_n \in W_{0}^i\) is reached.

4. Repeat steps (1)–(3).

A graphical description of this strategy is depicted in Figure 3. Starting from a state \(\nu_0\), the system executes the automaton \(A_{j_1}^i\) where the index \(j_1\) is chosen such that \(\nu_0 \in A_{j_1}^i\). Step (2) ensures that a state \(\nu_2 \in W_{0}^i\) (i.e., a state satisfying \(\psi_{g,i_1}\)) is eventually reached. This state \(\nu_2\) belongs to some set, say, \(W_{j_2}^i\) in the partial order \(\mathcal{P}^{j_2}\). The system then works through this partial order until a state \(\nu_3 \in W_{0}^i\) (i.e., a state satisfying \(\psi_{g,i_2}\)) is reached. This process is repeated until a state \(\nu_n\) satisfying \(\psi_{g,i_n}\) is reached. At this point, for each \(i \in I_g\), a state satisfying \(\psi_{g,i}\) has been visited at least once in the execution. In addition, the state \(\nu_n\) belongs to some set in the partial order \(\mathcal{P}^{j_1}\) and the whole process is repeated, ensuring that for each \(i \in I_g\), a state satisfying \(\psi_{g,i}\) is visited infinitely often in the execution.

**Theorem 1.** Suppose \(\Psi_{j}^i\) is realizable for each \(i \in I_g, j \in \{0, \ldots, p\}\). Then the receding horizon strategy ensures that the system is correct with respect to the specification (6), i.e., any execution of the system satisfies (6).

**Proof:** Consider an arbitrary execution \(\sigma\) of the system that satisfies the assumption part of (6). We want to show that the safety properties \(\psi_{g,i}, i \in I_g\), hold throughout the execution and for each \(i \in I_g\), a state satisfying \(\psi_{g,i}\) is reached infinitely often.

Let \(\nu_0 \in \nu\) be the initial state of the system and let the index \(j_1\) be such that \(\nu_0 \in W_{j_1}^i\). From the tautology of \(\psi_{init} \implies \Phi\), it is easy to show that \(\sigma\) satisfies the assumption part of \(\Psi_{j_1}^i\) as defined in (8). Thus, if \(j_1 = 0\), then \(A_{j_1}^i\) ensures that a state \(\nu_2\) satisfying \(\psi_{g,i_1}\) is eventually reached and the safety properties \(\psi_{g,i}, i \in I_g\), hold at every position of \(\sigma\) up to and including the point where \(\nu_2\) is reached. Otherwise, \(j_1 \neq 0\) and \(A_{j_1}^i\) ensures that eventually, a state \(\nu_1 \in W_{j_1}^i\) where \(W_{j_1}^i \preceq \psi_{g,i}, W_{j_1}^i\) is reached, i.e., \(\nu_1\) is the state of the system at some position \(l_1\) of \(\sigma\). In addition, the invariant \(\Phi\) and all the safety properties \(\psi_{g,i}, i \in I_g\), are guaranteed to hold at all the positions of \(\sigma\) up to and including the position \(l_1\). According to the receding horizon strategy, the planner switches to the automaton \(\mathcal{A}_{j_2}^i\) at position \(l_1\) of \(\sigma\). Since \(\nu_1 \in W_{k}^i\) and \(\nu_1\) satisfies \(\Phi\), the assumption part of \(\Psi_{j_2}^i\) as defined in (8) is satisfied. Using the previous argument, we get that \(\Psi_{j_2}^i\) ensures that all the safety properties \(\psi_{g,i}, i \in I_g\), hold at every position of \(\sigma\) starting from position \(l_1\) up to and including position \(l_2\) at which the planner switches the automaton (from \(A_{j_1}^i\)) and \(\Phi\) holds at position \(l_2\). By repeating this procedure and using the finiteness of the set \(\{W_{j_1}^i, \ldots, W_{j_p}^i\}\) and its partial order condition, eventually the automaton \(\mathcal{A}_{j_1}^i\) is executed which ensures that \(\sigma\) contains a state \(\nu_2\) satisfying \(\psi_{g,i_1}\) and step (2) terminates.

Applying the previous argument to step (3), we get that step (3) terminates and before it terminates, the safety properties \(\psi_{g,i}, i \in I_g\), and the invariant \(\Phi\) hold throughout the execution and for each \(i \in I_g\), a state satisfying \(\psi_{g,i}\) has been reached at least once. By continually repeating steps (1)–(3), the receding horizon strategy ensures that \(\psi_{g,i}, i \in I_g,\) hold throughout the execution and for each \(i \in I_g\), a state satisfying \(\psi_{g,i}\) is reached infinitely often.

**Remark 3.** For each \(i \in I_g\) and \(j \in \{0, \ldots, p\}\), checking the realizability of \(\Psi_{j}^i\) requires considering all the initial conditions in \(W_{j}^i\) satisfying \(\Phi\). However, as will be further discussed in Section VII, when a strategy (i.e., a finite state automaton satisfying \(\Psi_{j}^i\)) is to be extracted, only the currently observed state needs to be considered as the initial condition. Typically, the realizability can be checked symbolically and enumeration of states is only required when a strategy needs to be extracted [19]. Symbolic methods are known to handle large number of states, in practice, significantly better than enumeration-based methods. Hence, state explosion usually occurs in the synthesis (i.e., strategy extraction) stage rather than the realizability checking stage. By considering only the currently observed state as the initial state in the synthesis stage, the receding horizon strategy delays state explosion both by considering a short-horizon problem and a specific initial state.

**A. Remarks on the Partial Order \(\mathcal{P}\) and the Invariant \(\Phi\)**

Subsets \(W_{j_1}, \ldots, W_{j_p}\) of \(\nu\), the corresponding partial order \(\mathcal{P}\), the map \(F^j\) and the propositional formula \(\Phi\) are at the core of the receding horizon framework. Roughly speaking, \(\mathcal{P}\) provides a measure of “closeness” to the states satisfying \(\psi_{g,i}\). Since each short-horizon specification \(\Psi_{j}^i\) asserts that...
the system eventually reaches a state that is smaller in the partial order, it ensures that each automaton \( \mathcal{A}_j^i \) brings the system “closer” to the states satisfying \( \mathcal{Psi}_i \). The map \( \mathcal{F}^i \) thus defines the horizon length for these short-horizon problems. In general, the size of \( \mathcal{A}_j^i \) increases with the horizon length. However, with too short horizon, the specification \( \mathcal{Psi}_j^i \) may not be realizable. Since the computational complexity increases with the size of \( \mathcal{A}_j^i \), a good practice is to choose the shortest horizon, subject to the realizability of \( \mathcal{Psi}_j^i \), so that the automaton \( \mathcal{A}_j^i \) contains as small number of states as possible.

The propositional formula \( \Phi \) can be viewed as an invariant of the system. It adds an assumption on the initial state of each automaton \( \mathcal{A}_j^i \) and is introduced in order to make \( \mathcal{Psi}_j^i \) realizable. Without \( \Phi \), the set of initial states of \( \mathcal{A}_j^i \) includes all states \( \nu \in \mathcal{W}_j^i \). However, starting from some “bad” state \( \mathcal{Psi}_j^i \), there may not exist a strategy for the system to satisfy \( \mathcal{Psi}_j^i \). \( \Phi \) is essentially used to eliminate the possibility of starting from these “bad” states.

Computation of these critical elements requires insights for each problem domain. (See the example presented in Section VIII for such insights for an autonomous driving problem.) However, automatic construction of certain elements is possible, given other elements. For example, given an invariant \( \Phi \) and subsets \( \mathcal{W}_j^i \) and \( \mathcal{W}_j^i \) of \( \mathcal{V} \), construction of the partial order \( \mathcal{P}_i \) and the map \( \mathcal{F}^i \) can be automated. Such an automatic construction is discussed in detail in Section VII.

On the other hand, given a partially order set \( \mathcal{P}_i \) and a map \( \mathcal{F}^i \), one way to determine \( \Phi \) is to start with \( \Phi \equiv \text{true} \) and check the realizability of the resulting \( \mathcal{Psi}_j^i \). If there exist \( i \in I_g \) and \( j \in \{0, \ldots, p\} \) such that \( \mathcal{Psi}_j^i \) is not realizable, the synthesis process provides the initial state \( \nu^* \) of the system starting from which there exists a set of moves of the environment such that the system cannot satisfy \( \mathcal{Psi}_j^i \). This information provides guidelines for constructing \( \Phi \), i.e., we can add a propositional formula to \( \Phi \) that prevents the system from reaching the state \( \nu^* \). This procedure can be repeated until \( \mathcal{Psi}_j^i \) is realizable for any \( i \in I_g \) and \( j \in \{0, \ldots, p\} \) or until \( \Phi \) excludes all the possible states, in which case either the original specification is unrealizable or the proposed receding horizon strategy cannot be applied with the given partially order set \( \mathcal{P}_i \) and map \( \mathcal{F}^i \). Such an automatic construction of \( \Phi \) has been implemented in TuLiP, a Python-based software toolbox for receding horizon temporal logic planning [31].

In Section VIII, we illustrate a simple computation of \( \mathcal{W}_0^i, \ldots, \mathcal{W}_p^i \) for a particular system where the notion of “distance” to the goals can be easily defined. A systematic approach to construct \( \mathcal{W}_0^i, \ldots, \mathcal{W}_p^i \) for a general system, however, is subject to current research. Automatic construction of \( \Phi \) given \( \mathcal{P}_i \) and \( \mathcal{F}^i \) and automatic construction of \( \mathcal{P}_i \) and \( \mathcal{F}^i \) given \( \mathcal{W}_0^i, \ldots, \mathcal{W}_p^i \) and \( \Phi \) motivates the following iterative approach for computing these critical elements, provided that \( \mathcal{W}_0^i, \ldots, \mathcal{W}_p^i \) are given. First, start with an initial guess for \( \Phi \) (e.g., only exclude the unsafe states) and compute the corresponding \( \mathcal{P}_i \) and \( \mathcal{F}^i \). If the resulting \( \mathcal{P}_i \) and \( \mathcal{F}^i \) render \( \mathcal{Psi}_j^i \) unrealizable for some \( i \in I_g \) and \( j \in \{0, \ldots, p\} \), we recompute \( \Phi \) for this \( \mathcal{P}_i \) and \( \mathcal{F}^i \). Such an iterative approach is subject to current study.

**B. The Computational Complexity and Completeness of the Receding Horizon Strategy**

The receding horizon framework essentially reduces the original synthesis problem to a set of smaller problems. The partial order relation on \( \{\mathcal{W}_0^i, \ldots, \mathcal{W}_p^i\} \) induces a directed graph \( G^i \) whose nodes are \( \mathcal{W}_0^i, \ldots, \mathcal{W}_p^i \). In this induced graph, there is an edge from \( \mathcal{W}_0^i \) to itself and to each of the other nodes. For each \( j, k \in \{0, \ldots, p\} \) such that \( j \neq k \), there is an edge from \( \mathcal{W}_j^i \) to \( \mathcal{W}_k^i \) if and only if \( \mathcal{W}_j^i \prec \mathcal{Psi}_j^i \prec \mathcal{Psi}_j^i \) and there does not exist \( l \in \{0, \ldots, p\} \) such that \( \mathcal{W}_j^i \prec \mathcal{Psi}_j^i \prec \mathcal{Psi}_j^i \prec \mathcal{Psi}_j^i \). Suppose for each \( j \in \{0, \ldots, p\} \), there is only one path from \( \mathcal{W}_j^i \) to \( \mathcal{F}(\mathcal{W}_j^i) \) in \( G^i \). Then, we define the horizon length \( T_i \) for a short-horizon specification \( \mathcal{Psi}_j^i \) as the length of the path from \( \mathcal{W}_0^i \) to \( \mathcal{F}(\mathcal{W}_j^i) \) in \( G^i \).

Let \( N_G \) and \( N_E \) be the number of possible controlled and environment states, respectively, for a short-horizon problem with horizon length 1. Since the environment states for different short-horizon problems may be completely independent (e.g., whether there is an obstacle in a certain cell may not depend on whether there is an obstacle in other cells), it can be shown that the size of a short-horizon problem with horizon length \( T \) can be as large as \( TM_SM_T^T \). Recall that the computational complexity of the synthesis problem for GR[1] formula \( \text{O}(|\mathcal{V}|^3) \) where \( |\mathcal{V}| \) is the size of the state space. Hence, the computational complexity of solving each short-horizon problem is \( \text{O}(TM_SM_T^T) \) where \( T = \max_{i,j} T_i \leq p \). Since there are the total of \( (p+1)!/p! \) short-horizon problems where \( |I_g| \) is the cardinality of \( I_g \), the overall complexity of our receding horizon approach is \( \text{O}(p+1)!/p! (TM_SM_T^T) \). (Note that each of the short-horizon problems can be solved independently; thus, our algorithm is easily parallelizable.) In comparison, solving the original synthesis problem without applying the receding horizon planning procedure may lead to the complexity of \( \text{O}(pM_SM_T^T) \). Thus, if the horizon length is chosen such that \( T \ll p \), the receding horizon approach can significantly reduce the complexity of the synthesis problem.

In Section VIII, we provide an example of a synthesis problem that may not be solved without the receding horizon approach due to the size of the state space and illustrate the application of the receding horizon approach that allows such problem to be solved without excessive computational power. Other examples can be found in our previous work [14], [16].

On the other hand, the receding horizon approach is not complete. Even if there exists a control strategy that satisfies the original specification in (6), there may not exist an invariant \( \Phi \) or a collection of subsets \( \mathcal{W}_0^i, \ldots, \mathcal{W}_p^i \) that allow the receding horizon strategy to be applied since the corresponding \( \mathcal{Psi}_j^i \) may not be realizable for all \( i \in I_g \) and \( j \in \{0, \ldots, p\} \).

**Remark 4.** Traditional receding horizon control is known to not only reduce computational complexity but also increase the robustness of the system with respect to exogenous disturbances and modeling uncertainties [26]. With disturbances and modeling uncertainties, an actual execution of the system usually deviates from a reference trajectory \( s_d \). Receding horizon control allows the current state of the system to be continually re-evaluated so \( s_d \) can be adjusted accordingly based on the externally received reference if the actual execution of the
system does not match it. Such an effect may be expected in our extension of the traditional receding horizon control. Verifying this property is subject to current study.

VII. IMPLEMENTATION OF THE RECEDING HORIZON FRAMEWORK

In order to implement the receding horizon strategy, a partial order $\mathcal{P}^i$ and the corresponding map $\mathcal{F}^i$ need to be defined for each $i \in I_g$. We now present an implementation of this strategy, allowing $\mathcal{P}^i$ and $\mathcal{F}^i$ to be automatically determined for each $i \in I_g$ while ensuring that all the short-horizon specifications $\Psi^j_i, i \in I_g, j \in \{0, \ldots, p\}$, as defined in (8) are realizable.

Given an invariant $\Phi$ and subsets $\mathcal{W}^j_0, \ldots, \mathcal{W}^j_i$ of $\mathcal{V}$ for each $i \in I_g$, we first construct a finite transition system $T^i$ with the set of states $\{\mathcal{W}^j_0, \ldots, \mathcal{W}^j_i\}$. For each $j, k \in \{0, \ldots, p\}$, there is a transition $\mathcal{W}^j_i \rightarrow \mathcal{W}^k_i$ in $T^i$ only if $j \neq k$ and the specification in (8) is realizable with $\mathcal{F}^i(\mathcal{W}^j_i) = \mathcal{W}^k_i$. The finite transition system $T^i$ can be regarded as an abstraction of the finite state model $D$ of the physical system $S$, i.e., a higher-level abstraction of $S$.

Suppose $\Phi$ is defined such that there exists a path in $T^i$ from $\mathcal{W}_j^i$ to $\mathcal{W}_0^i$ for all $i \in I_g, j \in \{1, \ldots, p\}$. (Verifying this property is basically a graph search problem. If a path does not exist, $\Phi$ can be re-computed using a procedure described in Section VI-A.) We propose a hierarchical control structure with three components (cf. Fig. 4): goal generator, trajectory planner, and continuous controller.

**Goal generator:** Pick a sequence1 $(i_1, \ldots, i_n)$ for the elements of the unordered set $I_g = \{i_1, \ldots, i_n\}$ and maintain an index $k \in \{1, \ldots, n\}$ throughout the execution. Starting with $k = 1$, in each iteration, the goal generator performs the following tasks.

(a1) Receive the currently observed state of the plant (i.e. the controlled state) and environment.

(a2) If the abstract state corresponding to the currently observed state belongs to $\mathcal{W}^k_i$, update $k$ to $(k \text{ mod } n) + 1$.

(a3) If $k$ was updated in step (a2) or this is the first iteration, then based on the higher level abstraction $T^i_0$ of the physical system $S$, compute a path from $\mathcal{W}^k_0$ to $\mathcal{W}^k_i$ where the index $j \in \{0, \ldots, p\}$ is chosen such that the abstract state corresponding to the currently observed state belongs to $\mathcal{W}^j_i$.

(a4) If a new path is computed in step (a3), then issue this path (i.e., a sequence $\mathcal{G} = \mathcal{W}^l_0, \ldots, \mathcal{W}^m_i$) for some $m \in \{0, \ldots, p\}$ where $l_0, \ldots, l_m \in \{0, \ldots, p\}, l_0 = j, l_m = i, l_\alpha \neq l_\alpha'$ for any $\alpha \neq \alpha'$, and there exists a transition $\mathcal{W}^l_0 \rightarrow \mathcal{W}^l_{l+1}$ in $T^i_0$ for any $\alpha < m$) to the trajectory planner.

The problem of finding a path in $T^i_0$ from $\mathcal{W}^k_0$ to $\mathcal{W}^k_i$ can be efficiently solved using any graph search algorithm [32], such as Dijkstra’s and A*. To reduce the original synthesis problem into a set of problems with shorter horizon, the cost on each edge $(\mathcal{W}^l_{i_0}, \mathcal{W}^l_{i_\alpha})$ of the graph built from $T^i_0$ may be defined, for example, as an exponential function of the “distance” between the sets $\mathcal{W}^l_{i_0}$ and $\mathcal{W}^l_{i_\alpha}$ so that a path with smaller cost contains segments of shorter “distance”.

**Trajectory planner:** The trajectory planner maintains the latest sequence $\mathcal{G} = \mathcal{W}^l_0, \ldots, \mathcal{W}^m_i$ of goal states received from the goal generator, an index $q \in \{1, \ldots, m\}$ of the current goal state in $\mathcal{G}$, a strategy $F$ represented by a finite state automaton, and the next abstract state $\nu^*$ throughout the execution. Starting with $q = 1$ and $\nu$ and $\nu^*$ initialized as an empty finite state automaton and a null state, respectively, in each iteration, the trajectory planner performs the following tasks.

(b1) Receive the currently observed state of the plant and environment.

(b2) If a new sequence of goal states is received from the goal generator, update $\mathcal{G}, q$ and $\nu^*$ to this latest sequence of goal states, 1, and null. Otherwise, if the abstract state corresponding to the currently observed state belongs to $\mathcal{W}^l_{i_0}$, update $q + \nu^*$ to $q + 1$ and null.

(b3) If $\nu^*$ is null, then based on the abstraction $D$ of the physical system $S$, synthesize a strategy that satisfies the specification in (8) with $\mathcal{F}^i(\mathcal{W}^j_i) = \mathcal{W}^l_{i_0}$, starting from the abstract state $\nu_0$ corresponding to the currently observed state, i.e., replace the assumption $\nu \in \mathcal{W}^l_j$ with $\nu = \nu_0$. Assign this strategy to $\nu$ and update $\nu^*$ to the state following the initial state in $D$ based on the current environment state.

(b4) If the controlled state $\varsigma^*$ component of $\nu^*$ corresponds to the currently observed state of the plant, update $\nu$ to the state following $\nu^*$ in $D$ based on the current environment state.

(b5) If $\nu^*$ was updated in step (b3) or (b4), then issue $\varsigma^*$ to the continuous controller.

**Continuous controller:** The continuous controller maintains the most recent (abstract) final controlled state $\varsigma^*$ from the trajectory planner. In each iteration, it receives the currently observed state $s$ of the plant. Then, it computes a control signal $u$ such that the continuous execution of the system eventually
reaches the cell of \( D \) corresponding to \( \zeta^* \) while always staying in the cell corresponding to the abstract controlled state \( \zeta^* \) and the cell containing \( s \). Essentially, the continuous execution has to simulate the abstract plan computed by the trajectory planner. As discussed at the end of Section V-A, such a control signal can be computed by formulating a constrained optimal control problem and solved using off-the-shelf software.

From the construction of \( T^i \), \( i \in I_g \), it can be verified that the composition of the goal generator and the trajectory planner correctly implements the receding horizon strategy described in Section VI. Roughly speaking, the path \( G \) from \( W^i_j \) to \( W^i_0 \) computed by the goal generator essentially defines the partial order \( \mathcal{P}^i \) and the corresponding map \( \mathcal{F}^i \). For a set \( W^i_{l_i} \not\in W^i_0 \) contained in \( G \), we simply let \( W^i_{l_i} \prec W^i_{l_{i+1}} \), and \( \mathcal{F}^i(W^i_j) = W^i_{l_{i+1}} \), where \( W^i_{l_{i+1}} \) immediately follows \( W^i_{l_i} \) in \( G \). In addition, since, by assumption, for any \( i \in I_g \) and \( l \in \{0, \ldots, p\} \), there exists a path in \( T^i \) from \( W^i_j \) to \( W^i_0 \), it can be easily verified that the specification \( \Psi^i \) is realizable with \( \mathcal{F}^i(W^i_j) = W^i_0 \). Thus, to be consistent with the previously described receding horizon framework, we assign \( W^i_j > W^i_0 \) and \( \mathcal{F}^i(W^i_j) = W^i_0 \) for a set \( W^i_j \) not contained in \( G \). Note that such \( W^i_j \) that is not in the path \( G \) does not affect the computational complexity of the synthesis algorithm. With this definition of the partial order \( \mathcal{P}^i \) and the corresponding map \( \mathcal{F}^i \), we can apply Theorem 1 to conclude that the abstract plan generated by the trajectory planner ensures the correctness of the system with respect to the specification in (6). In addition, since the continuous controller simulates this abstract plan, the continuous execution is guaranteed to preserve the correctness of the system.

The resulting system is depicted in Fig. 4. Observe how this design corresponds to the planner-controller subsystem in Fig. 1 with the continuous controller having similar functionality as Path Follower, the trajectory planner having similar functionality as the composition of Traffic Planner and Path Planner, the goal generator having similar functionality as Mission Planner, and each of the sets \( W^i_1, \ldots, W^i_p \) being an entire road. Note that since the system is guaranteed to satisfy the specification in (6), the desired behavior (i.e. the guarantee part of (6)) is ensured only when the environment and the initial condition respect their assumptions. To moderate the sensitivity to violation of these assumptions, the trajectory planner may send a response to the goal generator, indicating the failure of executing the received sequence of goals as a consequence of assumption violation. The goal generator can then remove the problematic transition from the corresponding finite transition system \( T^i \) and re-compute a new sequence \( G \) of goals. This procedure will be illustrated in the example presented in Section VIII. Similarly, a response may be sent from the continuous controller to the trajectory planner to account for the mismatch between the actual system and its model. In addition, a local control may be added in order to account for the effect of the noise and unmodeled dynamics captured by \( \Delta \).

VIII. EXAMPLE

As an initial step toward correct-by-construction design of complex embedded control systems, we consider a simple autonomous driving problem in an urban-like environment. The state of the vehicle is the position \((x, y)\) whose evolution is governed by

\[
\dot{x}(t) = u_x(t) + d_x(t) \quad \text{and} \quad \dot{y}(t) = u_y(t) + d_y(t)
\]

where \( u_x(t) \) and \( u_y(t) \) are control signals and \( d_x(t) \) and \( d_y(t) \) are external disturbances at time \( t \). The control effort is subject the constraints \( u_x(t), u_y(t) \in [-1, 1], \forall t \geq 0 \). We assume that the disturbances are bounded by \( d_x(t), d_y(t) \in [-0.1, 0.1], \forall t \geq 0 \). More complicated dynamics of an omni-directional vehicle is considered in [14] for a simple road network.

We consider the road network shown in Fig. 5 with 3 intersections, \( I_1, I_2 \) and \( I_3 \), and 6 roads, \( R_1, R_2 \) (joining \( I_1 \) and \( I_3 \)), \( R_3, R_4 \) (joining \( I_2 \) and \( I_3 \)), \( R_5 \) (joining \( I_1 \) and \( I_3 \)) and \( R_6 \) (joining \( I_1 \) and \( I_2 \)). Each of these roads has two lanes going in opposite directions. The positive and negative directions for each road are shown in Fig. 5. We partition the roads and intersections into \( N = 282 \) cells (cf. Fig. 5), each of which may be occupied by an obstacle.

The planner-controller subsystem in Fig. 1 is implemented in a hierarchical fashion and naturally follows our general framework for designing a control protocol (Fig. 4). However, such a subsystem is typically designed by hand and validated through extensive simulations and field tests. Although a correct-by-construction approach has been applied in [33], it is based on building a finite state abstraction of the physical system and synthesizing a planner that computes a strategy for the whole execution, taking into account all the possible behaviors of the environment. As discussed in Section IV, this approach fails to handle even modest size problems due to its computational complexity. In this section, we apply the receding horizon scheme to substantially reduce computational complexity of correct-by-construction approach.

Fig. 5. The road network and its partition for the autonomous vehicle example. The solid (black) lines define the states in the set \( \mathcal{V} \) of the finite state model \( \mathcal{D} \) used by the trajectory planner. Examples of subsets \( W^i_j \) are drawn in dotted (red) rectangles. The stars indicate the positions that need to be visited infinitely often.
A. System Specification

Given the system in (9), we want to design a control protocol for the vehicle based on the following desired behavior and assumptions.

**Desired Behavior:** Following the terminology and notations used in Section III, the desired behavior $\varphi_s$ in (2) includes the following properties.

(P1) Each of the two cells marked by star needs to be visited infinitely often.

(P2) No collision is allowed, i.e., the vehicle cannot occupy the same cell as an obstacle.

(P3) The vehicle stays in the right lane unless there is an obstacle blocking the lane.

(P4) The vehicle can only proceed through an intersection when the intersection is clear.

**Assumptions:** We assume that the vehicle starts from an obstacle-free cell on $R_1$ with at least one obstacle-free cell adjacent to it. This constitutes the assumption $\varphi_{init}$ on the initial condition of the system. The environment assumption $\varphi_e$ encapsulates the following statements which are assumed to hold in any execution: (A1) obstacles may not block a road; (A2) an obstacle is detected before the vehicle gets too close to it, i.e., an obstacle may not instantly pop up right in front of the vehicle; (A3) sensing range is limited, i.e., the vehicle cannot detect an obstacle that is away from it farther than certain distance. (A4) to make sure that the stay-in-lane property is achievable, we assume that an obstacle does not disappear while the vehicle is in its vicinity; (A5) obstacles may not span more than a certain number of consecutive cells in the middle of the road; (A6) each of the intersections is clear infinitely often; and (A7) each of the cells marked by star and its adjacent cells are not occupied by an obstacle infinitely often.

In this example, we let this sensing range be 2 cells ahead in the driving direction. It can be shown [34] that the properties (P2) and (P3) and the assumptions (A1)–(A4) can be expressed in the form of the guarantee and the assumption parts of (6). Property (P4) can be expressed as a safety formula and property (P1) is a progress property. Finally, assumption (A5) can be expressed as a safety assumption on the environment while assumptions (A6) and (A7) can be expressed as justice requirements on the environment.

B. Correct-by-Construction Control Protocol

We follow the approach described in Section IV. First, we compute a finite state abstraction $D$ of the system. Following the scheme in Section V, a state $\nu$ of $D$ can be written as $\nu = (s, \rho, o_1, o_2, \ldots, o_M)$ where $s \in \{1, \ldots, M\}$ and $\rho \in \{+, -\}$ are the controlled state components of $\nu$, specifying the cell occupied by the vehicle and the direction of travel, respectively, and for each $i \in \{1, \ldots, M\}$, $o_i \in \{0, 1\}$ indicates whether the $i^{th}$ cell is occupied by an obstacle. This leads to the total of $2M2^M$ possible states of $D$. With the horizon length $N = 12$, it can be shown that based on the Reachability Problem defined in Section V-A, there is a transition $\nu_1 \rightarrow \nu_2$ in $D$ if the controlled state components of $\nu_1$ and $\nu_2$ correspond to adjacent cells (i.e., they share an edge in the road network of Fig. 5).

Since the only progress property is to visit the two cells marked by star infinitely often, the set $I_g$ in (6) has two elements, say, $I_g = \{1, 2\}$. We let $W_i^0$ be the set of abstract states whose $\varsigma$ component corresponds to one of these two cells and define $W_i^{\infty}$ similarly for the other cell as shown in Fig. 5. Other $W_j^i$ is defined such that it includes all the abstract states whose $\varsigma$ component corresponds to cells across the width of the road (cf. Fig. 5).

Next, we define $\Phi$ such that it excludes states where the vehicle is not in the travel lane while there is no obstacle blocking the lane and states where the vehicle is in the same cell as an obstacle or none the cells adjacent to the vehicle are obstacle-free. Using this $\Phi$, the specification in (8) is realizable with $F(W_j^i) = W_k^i$ where $W_j^i$ and $W_k^i$ correspond to dotted (red) rectangles in Fig. 5 that are two cells apart (e.g. $F(W_j^i) = W_{j+1}^i$). The finite transition system $T^i$ used by the goal planner can then be constructed such that there is a transition $W_j^i \rightarrow W_k^i$ for any $W_j^i$ and $W_k^i$ that are two cells apart from each other. With this transition relation, for any $i \in I_g$ and $j \in \{0, \ldots, p\}$, there exists a path in $T^i$ from $W_j^i$ to $W_0^i$ and the trajectory planner essentially only has to plan one step ahead. Thus, the size of finite state automata synthesized by the trajectory planner to satisfy the specification in (8) is completely independent of $M$.

Using JTLV [19], each of these automata has less than 900 states and only takes approximately 1.5 seconds to compute on a MacBook with a 2 GHz Intel Core 2 Duo processor and 4 Gb of memory. In addition, with an efficient graph search algorithm, the computation time requires by the goal generator is in the order of milliseconds. Hence, with a real-time implementation of optimization-based control such as NTG [35] at the continuous controller level, our approach can be potentially implemented in real-time.

C. Results and Discussions

A simulation result is shown in Fig. 6(a), illustrating a correct execution of the vehicle even in the presence of exogenous disturbances when all the assumptions on the environment and initial condition are satisfied. Note that the original synthesis problem requires considering 282 cells. Hence, without the receding horizon strategy, the discretized state space may contains as many as $10^{282}$ states, making this problem impossible to solve. In fact, JTLV fails to solve this problem with 4 Gb of memory due to an out of memory error. With the receding horizon strategy, only 9 of the 282 cells need to be considered in each synthesis problem. Thus, the number of possible states in the discretized state space reduces from $10^{282}$ to less than $10^{4}$, enabling JTLV to easily solve the problem as previously discussed.

To illustrate the benefit of the response mechanism, we add a road blockage on $R_2$ to violate the assumption (A1). The result is shown in Fig. 6(b). Once the vehicle discovers the road blockage, the trajectory planner cannot find the current state of the system in the finite state automaton synthesized from the specification in (8) since the assumption on the environment is violated. The trajectory planner then informs...
that can be correctly handled using the proposed response mechanism. This type of mechanism has been implemented on the autonomous vehicle built at Caltech for the DARPA Urban Challenge for distributed mission and contingency management [3]. Based on extensive simulations and field tests, it has been shown to handle many types of failures and faults at different levels of the system, including inconsistency of the states of different software modules and hardware and software failures. Another direction of research is to study an asynchronous execution of the goal generator, the trajectory planner and the continuous controller. As described in this paper, these components are to be executed sequentially. However, with certain assumptions on the communication channels, a distributed, asynchronous implementation of these components may still guarantee the correctness of the system. Finally, we want to extend the proposed receding horizon framework to other classes of temporal logics that allow better specification of temporal properties.
